ADDRESSES.

ADDRESS ON STATE MEDICINE—THE PEOPLE AND THE PUBLIC HEALTH MOVEMENT.

Delivered at the Forty-third Annual Meeting of the American Medical Association, at Detroit, Mich., June 7, 1892.

BY J. BERRIEN LINDSLEY, M.D.,
SECRETARY OF THE TENNESSEE STATE BOARD OF HEALTH.

In view of the great interest taken by the profession during the past year in the success of the measure brought forward by Dr. Comegys, I have thought that a succinct review of this important topic would not be inappropriate on the present occasion.

One day, while in attendance upon my second course of lectures in the University of Pennsylvania, sessions of 1842–3, it chanced that, examining the rich and varied stores of literature at a second-hand book store, my attention was arrested by an unpretending volume with a copious title page, the gist of which was: "An Inquiry into the Sanitary Condition of the Laboring Population of Great Britain." I purchased the book and devoured the contents, and perhaps no other volume has so influenced the thoughts, studies and pursuits of a long life as has that uninviting Government document, for the "Report" which it contained was the work of a master mind after mature investigation. Edwin Chadwick, the young and obscure Secretary of the "Commission" in that "Report," made a mark upon the civilization not only of the British Isles and of the wide expanded British Dominions, but upon the entire world.

The "Report" is dated London, May, 1842, and closed with conclusions: "First, as to the extent and operation of the evils which are the subject of the inquiry; secondly, as to the means by which the present sanitary condition of the laboring classes may be improved." These four concluding pages contain an admirable summary of practical public hygiene. No one now, fifty years after their date, can rise from their perusal without admiration of the genius which after two and a half years' study and observation elaborated them. As a practical application of the Baconian method of philosophy, they may be placed along side with the celebrated Essay of Dr. William Charles Wells, upon the phenomena of dew.

Fifty years ago, the fearful ravages of Asiatic cholera among the poor or laboring people of the British Isles was still matter of general comment. At that time also, the effects of the then recent revolution known as Parliamentary Reform were becoming manifest, insomuch that the wants and welfare of the people began to attract the attention of statesmen and party leaders, and have from that day to this been the main topics for legislation. The great feature of British history for the past half century has been the constant, steady elevation of the masses, and the one leading topic under this general head has been the public health. For proof, reference is made to the Acts of Parliament.

In 1853, the city of New Orleans was laid waste by an epidemic of yellow fever without parallel in all its history. An able Sanitary Commission was appointed by the Board of Health to make a report on this epidemic, which was published by authority of the City Council in 1854. It is a large and carefully prepared octavo, by able men. The treatise "Upon the Sanitary Condition of New Orleans," by Edward H. Barton, A.M., M.D., especially, was widely commended. Undoubtedly it was of great service to the Federal Government during the occupation of New Orleans, 1862–66 inclusive, when the city was noted for its cleanliness and healthfulness.

In this creditable municipal document, New Orleans made a step forward which, had it been kept up until now, would have placed it alongside of Calcutta or Bombay, with a population of over half a million, and commercial relations with the wide world. The calamitous experience of Tennessee in 1878 and 1879 reawakened popular interest in New Orleans upon local and maritime sanitation, and if the people do not go asleep, once more rapid progress towards its due position as one of the world's great cities may be expected.

One of the most remarkable examples of the people moving actively for sanitary reform, is found in the "Report of the Council of Hygiene and Public Health of the Citizens' Association of New York, upon the Sanitary Condition of the City," published in 1865. This massive volume, truly a manual of practical sanitation, was gotten up under the guidance of some twenty-four eminent surgeons and physicians of New York, who constituted the "Council of Hygiene." Names known, honored, reverenced and loved by us all occur in this glorious list. With one accord they all assigned the foremost place to Elisha Harris, their Secretary, who with Joseph M. Smith, President, and Willard Parker, Vice-President, constituted the executive of the Council. Dr. Harris' report upon the local sanitation of the city, its defects and remedies, has always been regarded as a model.

The influence of the British example in sanitary reform is nowhere better seen than in Massachusetts, where in 1850 was published "Report on the Sanitary Condition of Massachusetts," by Lemuel Shattuck, an eminent writer and legislator. This highly educated and most public-spirited community was among the earliest to comprehend the far-reaching benefits of State or preventive medicine. It was the first to establish a State Board of Health, which for the most part it has liberally supported, and which has brought rich returns to the State in more ways than one.

It will thus be seen that in America as well as in Britain, sanitary reform was inaugurated not so much by the medical profession as by the general public, looking at first to its protection from disastrous epidemics, and next to relief from preventable diseases and improvement in daily health. It may be looked upon as an outcropping of the well-defined tendency of the times towards the elevation of the people. An epoch-making tendency, germinated by the American Revolution of 1776, which startled the world by that of France, 1789, and which, by the general consent of thinking people with all shades of opinion, is about to accomplish social results and changes, most likely improvements, not less in magnitude than was witnessed in the fourth century, when Christianity supplanted Paganism in the Roman world.

Though not a medical movement, yet from the knowledge required to put it forward, medical men were naturally from the start called in by its promotors, and very soon took the lead. This is especially true in America, where in nearly every instance of city or State progress physicians have been the pioneers. So much is this the case that there is now some danger of the public looking upon sanitation as belonging *exclusively to our profession.* No greater mistake can be made. For it is law, and not medicine, that is most concerned. The prevention of disease and its cure are two very different affairs. Let every man be a law unto himself, every household a separate unit, and society would soon be reduced to savageism so far as health is concerned, while practitioners of medicine would reap a rich harvest. On the other hand, so soon as households are contiguous every man becomes his brother's keeper, and the law must come in with its commands and its penalties.

Of recent years the medical profession has been endeavoring to remedy this error by calling in the assistance of the people through voluntary associations composed of all descriptions of persons, and with remarkable success. Medical science can dictate what kind of laws should be made for the promotion of the public health, but is powerless to enforce these laws. Here the people in their individual and collective capacity must act. They must realize that they are the Government, and if the great city is hideously unclean, so as to merit the chastisement of a dozen Rudyard Kiplings, and the little village so nasty that no one wishes to keep his family in it, they alone are responsible.

If time allowed, we could fill pages with the enumeration of citizens' volunteer societies, from the "American Public Health Association," founded in 1872, now embracing the entire North American Continent, to "The Ladies' Health Protective Association of the City of New York," established some twelve years later, and which has already accomplished great good. These associations are doing much to correct the idea that sanitation is a merely medical business. If as active and as potent for another decade as in the past one, that mistake will be eradicated.

A powerful auxiliary in this line is the influence of the magazines and weekly publications. These abound in well written and highly scientific articles on all topics of public no less than private hygiene. Medical science is fast becoming public property. The magnificent progress upon which we so much pride ourselves of late years is the result of advances in chemistry, physics and biology. These belong to the great republic of science, and not to the mere province of medicine. We are the debtors of the scientists; not they to us.

Medicine, like theology and law, is rapidly passing from the esoteric to the exoteric stage. It can no longer be a secret or mystic calling, looked up to with the reverence and fear begotten of ignorance. Hence it follows that if the profession wishes to maintain the position hitherto freely accorded to it by the people as leading in sanitary reform, it must become a body of scientists. This it will be when, in due course of time, the improvements now rapidly taking place in the medical curriculum become universal.

At present, the special topic connected with the sovereign people and its action upon the public health in which this body takes the most interest, is the connection of the Federal Government with the work. Strangely enough, of all nations the American Republic is most backward in looking to the public welfare as it respects health. And that too, when there are certain great features which make the entire people one, with corresponding wants to be supplied, which only a rich and powerful Government can effect.

No sooner were local boards of health tolerably numerous in the United States and the establishment of State Boards well under way, than the necessity of Federal action was keenly felt, not only for coördinating and completing the work of these bodies, but also for accomplishing indispensable functions beyond the power of our largest cities, or most powerful and wealthy States. The argument for this Federal action is well stated by one of its earliest advocates, if he be not the first—the late Christopher C. Cox, M.D., LL.D., President of Board of Health, Washington, D. C., who as far back as 1871, devoted much time and energy in making known his views. I quote from the first volume of "Reports and papers of the American Public Health Association," pp. 523, 524.

"Important as is the preservation of health and prevention of disease, both in regard to individuals and communities, and early as the subject forced itself upon human attention, public hygiene never, until a comparatively recent period, assumed its deserved position, or became entitled to consideration as a distinct science. The frequent and terrible invasions of epidemics, and the occasional increased violence of endemic maladies, stimulated energy and research in the discovery of suitable means to prevent or modify the ravages of these relentless foes to health and life. The public mind became imbued with the imperative demand of such measures. Boards of health were everywhere established, the result of whose labors has been very largely aided by successful researches in the kindred sciences of physiology, pathology and chemistry. Who at this day questions the value of these local organizations?

"The idea of a central bureau of health is not perhaps altogether original with the author of this essay. More than fifteen years ago, an able treatise was issued from the English press, by Henry W. Rumsey, entitled "Essays on State Medicine." The original design of the work comprehended the establishment of a Central Sanitary Board under Government direction. The scope of the treatise was at first very extended, embracing the "bearings of preventive medicine upon the several questions of general legislation, as education, public works, popular representation, agriculture, commerce, etc., and to inquire how far hygienic principles had been, or might be recognized in the framing or execution of various measures of National inquiry and reform. Since the publication of this work, England has organized a central health department, and is now seriously contemplating a ministry of public health. Prussia, under the direction of Bismarck, is engaged in similar movements, while Germany has been long distinguished for her comprehensive National health code. The object of these efforts in Europe is what we desire to accomplish in this country, namely: the collection of the largest amount of correct information upon every subject connected with the public health, and sow it broadcast over the land, for the benefit of the whole people.

"Regarding the constantly increasing sanitary wants of our country, its extensive geographical area and varieties of climate, its climatic zones marked by certain morbid peculiarities and endemic diseases, its hydrology, the thousand agencies and influences threatening its soundness, it occurred to me that our government should advance among the first to conserve the health of its population, and avert the disasters which menace it. With this view, I prepared in 1871 the plan of a National bureau of health. This was subsequently submitted, as you are aware, at a meeting of sanitarians, representing the different sections of the country assembled at New York, and indorsed by them in a series of commendatory resolutions. Since then an 'American Health Association' has been organized, embracing in its membership the leading scientists and sanitarians of the United States and Canada; and at their last meeting, a special committee, of which I am chairman, was appointed to report upon the 'necessity of a national sanitary bureau.' I allude to these facts for the purpose of showing that I have not urged this subject prematurely before Congress, but after full and earnest interchange of views with others whose high standing entitles their views to credit and respect."

The American Public Health Association was organized in 1872 by a conference of prominent Sanitarians. At this conference Dr. Cox again brought his plan forward. At the first Annual Meeting of the Association, Cincinnati, 1873, Dr. Cox made an elaborate report from which the above extract is taken. This report appears at length in the first volume of "Public Health", 1875. Thus it seems that the ideas of Dr. Cox were widely and persistently pressed upon the attention of sanitary bodies, and are still bearing fruit.

Had this effort been properly seconded by the medical profession, the Bureau would doubtless have been established. Nothing came of it, and when the Yellow Fever epidemics of 1873 and 1878, and also the widely spread devastation of cholera in 1873, terrified the land, no resistance was made. However, this very helplessness aroused the people, especially those of the Interior Valley which had most suffered. At the Richmond meeting of the American Public Health Association, 1878, action was taken which resulted in the creation of the "National Board of Health," by Act of Congress, approved March 3, 1879. Great pains were exercised to harmonize this Board with State and Local Boards. Its members appointed by the President were typical representatives of the profession. When organized on the second of April, 1879, these members chose as their President and Vice-President, two physicians of whom it is safe to say that they had the confidence and esteem of the whole country. This confidence was soon tested by the second Memphis epidemic, that of 1879, which broke out in mid-summer. In coöperation with the Tennessee State Board of Health, Memphis was isolated, or quarantined, the destitute cared for and no spread of the disease allowed. Immediately upon its abatement, in conjunction with the Memphis authorities, the National Board entered upon that course of sanitary re-generation which has since made the said city a favorite example for sanitarians at home and abroad.

How it came to pass that after a few years, just sufficing to prove its great capacity for good, it was starved to death, no one has satisfactorily explained. Perhaps it was owing to the fact of not being in the usual model of government offices at Washington. Had it been a Bureau in the Department of the Interior, those familiar with Washington, hold that it would now be in existence, and in a fair way to become a Department, with or without a seat in the Cabinet.

Concurrent with the decline of the National-Board of Health has been the expansion of the Marine Hospital Service, which in some respects already represents the government in the field of preventive medicine. *De facto* the U. S. M.-H. S., is one of the most important "Bureaus" at Washington both as to expenditures and duties. It has as its head an accomplished medical gentleman who owes his position to merit alone, and who is virtually a "Medical Commissioner of Health." Some have maintained that the readiest way to reach the desired end would be to change this "Service" into a "Bureau of Public Health," leaving it what functions it now has and adding others. What is now the very important "Weather Bureau of the Department of Agriculture" began in a very insignificant way as the work of "the Chief Signal Officer of the Army." Truly a great oak from a little acorn. The overshadowing postal department began in an equally obscure manner about a century ago.

Prior to 1862 "Agriculture" was hid away in the Patent Office, itself a Bureau in the Department of the Interior. It then became a Department with a commissioner at its head. Recently its head has become a Secretary with his place in the President's Cabinet. And now it proudly holds its position as second to no other branch of the people's government.

Growth, or evolution if you prefer, seems to be the law at Washington. Sooner or later the Department of Public Health will exist as a part of the National government. This department will embrace under its capacious folds several functions now partially filled by services attached to different departments. In the meantime the more efficient these services are rendered, the more complete will be our Ministry of Public Health when created.

Maritime quarantine is by common consent deemed a foremost duty of the Federal government. The States have been tried and found wanting as safeguards against the importation of those pestilential exotic diseases, most feared by the American people. This duty in a partial way is now confided to the United States Marine Hospital Service. That in strumentality should in this respect be made perfect and thorough, fully equipped for watching all our immense lines of ocean, gulf and lake coasts. This is so generally recognized that a very little effort by the profession speaking for the public, would secure the necessary appropriation.

One great Bureau in a Department of Public Health would be that of vital statistics. This touches every man, woman and child in all our 70,000,000, even more than does the Weather Bureau, which is an exceedingly popular concern with the people. Without vital statistics, reliable and not guesses, the servants of the Public Health are working in the dark. The birth rate, the death rate, the prevalence of diseases as shown by mortality tables are fundamental data for our guidance.

Reliance upon State efforts to furnish these is shown by the experience of more than a century to be absolutely futile. There is an existing agency of the government known as the Census Office in the Interior Department, which every ten years has an immense work in hand. For collecting vital statistics, this service should be perpetual. It is quite safe to estimate that an expenditure of about half a million of dollars annually, would maintain a system of registration recording the wanted facts connected with each birth and death in the entire vast Republic. This system of registration can easily coöperate with State and Local Boards, only it would be uniform and paid for out of the general fund. It is hardly necessary to elaborate this idea. The absolute necessity of such a registration for public health purposes, and its manifold benefits to the business interests of all parts of the country are manifest to the most casual observer.

Another much wanted sanitary work directly within the province of the general government is the execution of a minute topographical survey of the entire country, and the mapping its results on a scale so extensive as to embrace every important local feature. Such maps are needed by the agricultural, commercial and military interests of the people. For all public health improvements, these maps are indispensable. For health purposes the whole seventy or it may be one hundred and seventy millions of people constitute but one family. The immense area of three million and more square miles, with its circumambient atmosphere is only one great big habitation. As the Weather Bureau keeps us constantly informed of aerial changes, so should the permanent features of the house be made known once for all by an analogous Bureau, whose field is the land, and the water in and around the land. Such surveys and such minute maps splendidly executed have long since been commenced or finished by Great Britain, Spain and other European governments. Every advanced nation in the world recognizes the value of this work as a contribution to general science and as an aid to home development. It pays well and cannot be done by the separate fragments of a great country. It can be undertaken alone by a great and rich people.

This survey and mapping has been commenced on a small scale and for two definite purposes, years ago by the United States government. Under the Treasury Department there is the Coast and Geodetic Survey, which under the superintendence of very able scientists has accomplished results of immense value to the commercial and naval interests of America. Extensive as is this survey, it is but an item in the great scheme outlined above, though the indispensable beginning of the same.

In the Department of the Interior we find the U. S. Geological Survey a complement to the last mentioned. The results of both these surveys combined make a useful whole.

There is a function of the National Public Health work which is now performed in a disconnected manner by several Bureaus and offices at Washington. I refer to scientific research and outfit of value to State Preventive Medicine, beyond the scope or the obligations, no less than the means of the individual States. Such researches are made under special provisions in Acts of Congress, sometimes by the Marine Hospital Service and its able corps of experts; sometimes by the Smithsonian Institution; at others by Commissioners appointed by the President for a definite purpose. A recent result of the latter is the valuable cyclopædic "Report on Cholera in Europe and India," by Dr. E. O. Shakespeare, who was appointed by President Cleveland, Oct. 1, 1885, and who on Nov. 17, 1890, transmitted his great work to Secretary Blaine, after having given five years of travel and study to its preparation, "all voluntary and without pay for personal service." Perhaps there is no other instance of an individual holding the high appointment of Commissioner from our National government, acting in so patriotic and liberal a manner, and furnishing an example so worthy of imitation by men of means and culture. Well may the medical profession take an honest pride in such a worthy colleague.

The outfit of special interest and usefulness to the workers in sanitary progress at present furnished by the Washington Government without reference mainly to this purpose, are twofold. The Museum of Hygiene under the care of the Department of the Navy. This is a new establishment, which though supported by meagre appropriations, has already demonstrated a capacity for very valuable services. If the plans of those in charge are carried out, but a few years will elapse ere a constant stream of pilgrims will visit Washington from cities and towns in order to get practical knowledge, which otherwise would cost long and tedious research. The medical profession should see to it that this very important museum is not overlooked by Congress.

But best known at present is the "Library of the Surgeon General's Office of the U. S., Army." Under this insignificant title, indicating a very limited use, has in a few years grown up one of the most complete medical libraries in the world. Also it is in buildings, equipment, volumes and management a leading institution of the Union. It has given honorable renown to our country, among all scientists abroad. It is the great storehouse for information freely accessible to all who devote their energies to healing or preventing disease. Who would imagine that at this late day any statesman at all in contact with the one hundred thousand practitioners of medicine in these States, would dream of reducing its modest allowance of ten thousand dollars per annum, to the miserable pittance of one half that amount?

The general government does far more for sanitary science than at first sight appears, or than it has had credit for. This is evident from the above rather imperfect analysis of its disjointed work.

If a Department of Public Health were now created, with its head holding a seat in the President's Cabinet, it could at once be furnished with an ample number of Bureaus to give it a high place in the public esteem, and to keep that head fully as busy as any of his colleagues. The U. S. Marine-Hospital Service, expanded as it ought to be would furnish at least three Bureaus with a number of drawers each. Namely, those of Maritime Quarantine, the Marine Hospitals, and Scientific Researches. The Coast Survey, the Geological Survey, the Great Medical Library and Museum, with the Museum of Hygiene would constitute also ample Bureaus for first class Commissioners. While the Bureau of Vital Statistics would soon become almost a Department by itself.

Let it be well understood that the elimination of all these offices from the departments now looking after them,in order to make up a great Department of Public Health, can take place with no injury, but rather a relief to the present Secretaries. The overburdened Treasury Department can readily spare the U. S. Marine-Hospital Service and the Coast Survey. So can that of the Interior, the Census Office and Geological Survey. War has ample scope and verge enough without the Medical Library, as has the Navy without the Museum of Hygiene.

In looking over the transactions of the American Medical Association for the past twenty years one is impressed with its indifference to the work of the Federal Government in promoting the public health rather than otherwise. As late as 1877, the expressions were that it was too early to move in this direction, and that action should be deferred until State Boards of Health were generally created. The success of the American Public Health Association before Congress in 1878-9, proves that this was an erroneous idea, and that the people were ahead of the profession in sanitary progress.

At the Washington meeting of this body, 1884, Prof. Deering J. Roberts, M.D., of Tennessee, in an elaborate address on State Medicine, strongly argued for a "Minister of Public Health." Had this thesis been taken up and pushed by the medical profession as it should have been, ere now the *projet* would have been *un fait accompli.*

More recently the American Medical Association has become alive to the necessity of action. This is evidenced by the greatly increased interest taken in the Section of State Medicine, which for years had an existence almost nominal. Also by the tone and substance of the addresses from our presidential chair.

The able and well considered efforts of Dr. C. G. Comegys have at last awakened this Association to an interest never before manifested by it in behalf of National sanitation.

Now there should be no uncertain action. The other chartered and National organization, which for twenty years persistently worked on this line, and at one time with marked results,has a standing Committee on "National Health Legislation." This Committee is composed of eminent men from all sections of the great republic and is charged with the duty of keeping the subject before the National Legislature. Would it not be well to have a similarly empowered permanent Committee from this body, which acting in concert with the American Public Health Association, the American Association for the Advancement of Science, the Congress of Physicians and Surgeons and other scientific bodies should do efficient service in advancing the cause?

In concluding this brief outline of a grand movement, let it be emphatically stated that of all the reforms projected and pushed in this busy nineteenth century, none touches the great masses more closely than this. The people, the working and voting people are with us. Read the manifestoes of the numerous labor organizations of America in which are gathered not only the sinews but the brains of a mighty people, and you will see as a keynote running through the whole diapason, the sacredness and value of home, of wife and children. And hence constant allusions to sanitary wants and improvements. No better sign for the future permanence, grandeur and happiness of the greatest Nation upon whose domain the sun has as yet shed its rays, could be desired.

DELIVERY THROUGH THE ABDOMINAL WALLS vs. CRANIOTOMY, IN OTHERWISE IMPOSSIBLE BIRTHS.

Read before the Section of Gynecology and Obstetrics, at the Forty-third Annual Meeting of the American Medical Association, at Detroit, Mich., June, 1892.

BY GEORGE I. McKELWAY, M.D.,

GYNECOLOGIST AND OBSTETRICIAN TO THE PHILADELPHIA HOSPITAL.

It is not the purpose of this paper to decide what degree of contraction or what other obstructions render birth through the natural passages impossible, nor is it its purpose to consider the indications for inducing premature labor, but simply to discuss which shall be done—some form of Cæsarean section or a craniotomy in cases in which election between them is called for and possible.

Of course the first and most important thing to be considered (not the *only* question however), is the maternal risk or mortality under the respective operations. If it should be proven that the one in all cases or in most cases, is exceedingly more dangerous to the mother than the other, our action should be largely guided by that determination. There are conditions which modify this mortality in individual cases; whether, on the one hand, the mother through long labor and ignorance or neglect, or careless handling on the part of her attendants, has become septic and so exhausted that her life would be very greatly imperiled by the shock of the Cæsarean section, and, what should be considered coincidently, whether the fœtus still shows evidence of so much vitality as would justify subjecting the mother to added risk for the mere possibility of saving it. On the other hand there must be considered the risks of embryotomy in the individual case; whether the destruction and piecemeal extraction of the child may not be as dangerous or more dangerous, to the mother, all things considered, than is the extraction of even a dead fœtus through the abdominal walls. Into the discussion of possible individual cases, however, it is not my purpose to enter.

The primary and basic question, so far as the maternal risk only is concerned, would seem to be that of the relative mortality of embryotomy done deliberately in suitable cases before the mother is either septic or exhausted, and Cæsarean section, either the improved Cæsarean or Porro operation, done under the same conditions. The writer despairs of answering this question for the reason that craniotomy has not yet been done in this premeditated way sufficiently often to determine what its mortality would be were it so done. The woman is usually permitted to exhaust, and possibly infect herself, maybe by days of fruitless efforts to deliver herself, and by attempts on the part of her attendants to deliver by forceps or version or both, before craniotomy is performed.

The operation of craniotomy is so repugnant, excepting as the last possible resort, that even when practically convinced that it must be done later, if labor and attempts to deliver by forceps or version are permitted to proceed, many obstetricians, even the most skilful, hope against hope and for their own sake, as well as for the sake of the parents and friends, permit such fruitless labor to go on and attempt all other procedures until it is demonstrated to all interested that the delivery is impossible, before resorting to craniotomy; and the writer believes, because of the nature of the operation, that this will always be the case in general practice where embryotomy is held in thought as a possible last resort and as an excuse for avoiding a section. So that it is impossible to obtain sufficient data upon which to base a statement as to what the maternal mortality would be were craniotomy deliberately resorted to at the very commencement of labor.

This is not true, however, of Cæsarean section. In these later days it has been resorted to deliberately and with all the conditions favoring its successful determination, and our conclusions as to the possibilities of this operation should be based on the results of it so done. It is unnecessary to state that our estimate of the danger of either procedure must not be based upon results obtained before the Listerian era. Such results have no relation whatever to the mortality that may be expected from either operation in these days. Surgery, and especially obstetrical and abdominal surgery, is a new art, and it is no more fair to judge what the results will be in the future by the statistics of either operation performed before the time mentioned than it would be to judge of the mortality of ovariotomy tomorrow by the results of Washington L. or John Atlee's cases.

Besides the question of the maternal risk there comes the question, which has not heretofore been sufficiently considered and which it has been the custom to ignore, and that is, as to what amount of risk the mother is to be subjected in order that her child's life may be saved. The purpose of pregnancy is a living child; and this should never be forgotton. Supposing, for instance, that the mortality for Cæsarean section in cases parallel to a special case that may be under consideration, is twenty per cent. to the mother and five per cent. to the child. Supposing further that the mortality of embryotomy in such a case is estimated at eight per cent., is the mother to have all the chances for life that she may possibly have and the child to have none? Or shall the mother relinquish twelve additional chances for her life, still having eighty in the hundred, in order that her child may have ninety-five of its hundred? Or shall the child give up its whole hundred chances in order that the mother, who, in a Cæsarean section, would already have eighty in the hundred, may have twelve more?

Has the unborn child any right the obstetrician is bound to respect?

Let us determine first, as accurately as we can, what the mortality of embryotomy is, done under as good conditions as we should be likely to find. I am perfectly aware that some obstetricians claim that in properly selected cases, embryotomy is without a mortality. For instance it is stated that Leopold has had ninety-two craniotomies without a death and Dr. Robert A. Murray, in the *New York Medical Journal* of June 1, 1890, says, while pleading for the Cæsarean section, "my own statistics are that in over twenty craniotomies performed under strict antiseptic precautions, I have not had any mortality. About half of these were done on the after coming head." And yet the fact remains that women die after it and apparently in consequence of it. It has its serious risks. There are the risks of sepsis, and of hæmorrhage and of shock.

The best collection of statistics as to its mortality that I know of, is to be found in Dr. E. P. Davis's article in the second vol. of the American System of Obstetrics. These statistics represent the operation as done since the introduction of antiseptic measures. He quotes the reports of Spiegelberg's cases, of Wyder's, Merkel's, Olshausen's, Winckel's, Jaggard's Report of Carl Braun's cases, Präger's cases, Determann's Statistics and Caruso's Statistics. The death rate in these cases runs from one and four-tenths per cent. to thirteen and three-tenths per cent., and the average mortality of the operators quoted is 7.95 per cent. So that it is fair to say that the maternal mortality, in such cases as those in which embryotomy has hitherto been done by the best operators under presumably the best condition, is *about* eight per cent.

In addition too, to the risk to the mother's *existence* we should not lose sight of the question as to what her condition in after life may be: the risk of laceration, of fistulæ, of injury to ovary, tube or uterine body, and the possibility that in many cases an operation more serious than a deliberately performed Cæsarian section may be necessary before the mother will have again a condition of health making life worth living. Furthermore there is the awful suspense to the woman and her friends, the long, dreadful, painful ordeal and the disappointment that comes from the fact that after all she has gone through during her pregnancy and her labor, the purpose of it all, the birth of a living child, has not been achieved.

We must compare the mortality of the Cæsarian section with that of the operation we have just considered. For this operation also it is claimed that there should be no death rate. I quote Dr. Egbert Grandin, who says "The Cæsarian section performed advisably ought not to have a mortality rate." But as in the case of the other operation, we find that women do die after it and apparently in consequence of it. It has its risks; those of sepsis and of hæmorrhage—not so serious, in my judgment, as they are in embryotomy—and the risk of shock, which is possibly greater.

Dr. R. P. Harris[1] states that Sänger has operated eight times consecutively without a maternal death, and Dr. Cameron, of Glasgow, ten times with but one death. In this country within the last few years Dr. Howard A. Kelly has operated four times without a death, Dr. Wm. Goodell twice without a death, and Dr. Lusk four times—losing one patient. Dr.

---

[1] Gynecological Transactions, 1891

Joseph Price, of Philadelphia, has performed the Porro operation five times with no deaths. Leopold, in his cases from 1884–88 inclusive, has had a death rate of 8.6. These were Porro operations. Zweifel lost but one woman and one child in eighteen (new operation) cases. The woman that he lost was eclampsic when operated on, and, it is claimed, died from eclampsia. Dr. Harris, in the *American Journal of the Medical Sciences*, October, 1891, quotes the statistics of Leipzig, furnished him by Prof. Sänger, showing thirty-eight cases by eight operators with three maternal deaths and four children lost. Two of the women died of septic peritonitis, the other was Zweifel's case just spoken of. These thirty-eight cases include Zweifel's eighteen cases. Dr. Harris further says (it is impossible to avoid quoting Dr. Harris, for he has contributed much to the study of this subject) that in the Maternity of Allgemiene Krankenhaus, Vienna, there were twenty-five Cæsarean deliveries by both the improved and the Porro method from 1886–89 with only two women lost and all the children were saved.

I do not care to go further into statistics. Such inquiry, unless limited, is apt to prove too much or too little. The figures I have quoted, by showing what *has* been done, prove what *can* be done, and unless the world stands still, better results than these will be achieved in the near future. From these figures I believe it to be fair to state that the mortality of the improved Cæsarean section, done in women not exhausted by labor, and done under proper antiseptic or aseptic precautions, by skilful operators, is not over 10 per cent.; and that the mortality of the Porro operation under the same conditions will not greatly, if at all, exceed this. Now even if the contention that has been made, be granted, and we decide that, while Cæsarian section has a death rate of about ten per cent., craniotomy has no death rate at all, I do not conceive that this is an overwhelming argument in favor of the latter operation in the class of cases that we are considering. Our training and traditional thought is such, that without an effort, we do not think at all of the living unborn child and we leave it out of our calculations. Parry in his classical paper read some years ago before the Philadelphia County Obstetrical Society emphasizes this absolute ignoring of the child's life, by calling attention to its value in these words—speaking of the statistics of the mortality of the seventy cases of craniotomy he quotes, he says "If we remember that in the seventy cases included in the appended table only thirty-three out of the 140 lives were saved, the truth becomes almost too horrible to contemplate."

I do not regard the physician as primarily the conservator of individual life; his duty is to all human life and to its conservation, and his obligation is as great, other things being equal, to life incarnated in one body under his care as to it in another. I grant that things are not equal as between the mother and her unborn child, but they are very much nearer so than is argued by the habit and thought of many obstetricians.

There are those, however, who believe that even considering the mother only, Cæsarian section done under proper conditions, is as safe for her as is craniotomy; and the safety of the former operation, compared with the latter, increases very greatly as her pelvis narrows. For instance Dr. Lusk says, speaking of craniotomy, "In the hands of an operator of limited experience, I believe the Cæsarian section, when timely made, offers ordinarily to the mother a better chance of recovery."

Dr. Harris says,[2] "The new Cæsarian operation in the hands of a Zweifel or a Leopold, in a case of extreme rachitic deformity of the pelvis, is less fatal than an embryotomy is in skilful hands where there is the same degree of pelvic stenosis."

Dr. Grandin in the *New York Medical Record*, of June 6, 1891, states that the operation (Cæsarian section) is not so dangerous as the removal of the uterus for fibroid tumors. He further states that the technical skill for a difficult craniotomy needs to be as great as for an ordinary Cæsarian section.

Dr. R. A. Murray[3] of New York, says in speaking of a case in which Cæsarian section was done: "but the operation must be contrasted with craniotomy, the only other resort in this case. Formerly Cæsarian section was only resorted too where craniotomy was out of the question, but now, where it becomes a question of saving the child, I hold that the preference should be given Cæsarian section, for, if the case be taken in time, we find that our statistics will become more favorable for the mother—even more favorable than craniotomy. I have nothing to complain of in craniotomy. I have not lost a patient, although I have had a number of cases. Yet I know operators who still maintain that Cæsarian section should not be done except for absolute indications. In one instance the operator spent three hours in relieving the patient of the child. She lived, but she had a torn vagina, a lacerated cervix, and an infection afterward which left her worse off than if she had been dead. I think we must take the after condition of the patient into consideration. Where it becomes a question whether to do laparotomy or craniotomy, I think that even the average practitioner, certainly the average laparotomist, will get about as good results from Cæsarian section, for the mother, and the child is saved."

Dr. Egbert Grandin said, in the discussion which followed this paper, "the statistics of Cæsarian section as clearly set forth in the paper which our distinguished colleague has read, fortifies me in the position which I have sometime held—that the time is ripe for the deliberate *election*, in hospital practice at any rate, of the Cæsarian section over embryotomy. Once let it be proven that we can save the child through the elective section, and yet not imperil the woman to a greater degree than does embryotomy, and there ceases to be an excuse for the destruction of the living fœtus."

Dr. Parry says in his memorable paper, from which I have previously quoted, "the Cæsarian section is much more easily done than craniotomy when the anterio-posterior diameter of the superior strait is two inches or below it."

The writer has heard Dr. Joseph Price, of Philadelphia, speaking in the obstetrical society upon the small risk in the Porro operation when properly done, say that he believed that he had done his last elective craniotomy, and the honored president of this section has expressed about the same conviction to the writer.

Dr. A. P. Dudley, of New York, in speaking of the danger of Cæsarian section, says "the elective Cæsarian section should have a lower mortality than the average ovariotomy." This because of there being no adhesions, no uncontrollable hæmorrhage and the avoidance of sepsis.

[2] Gynecological Transactions, 1891.

[3] Gynecological Transactions, 1891.

So long as it seemed that in doing the Cæsarian operation upon a pregnant woman in the case of whom craniotomy might have been done, the result was almost invariably only the possible saving of a frail, infantile life at the expense of the mother's existence, there could be no question as to which operation should be performed. But that day has gone by and it is not to-day at all a question of the *saving* of one life at the expense of another, but merely a question of a not very great additional *risk* to one life in order that the other may be saved and that the purpose for which the woman entered into the marital relation and for which she became pregnant, might be achieved. Speaking of this question of risk, Dr. Grandin pertinently asks, "if the woman may take her life in her hands in order to get rid of, we will say a cystic ovary, *by what right* may she refuse to run about the same risk to save the fruit of her womb?" He further says [4] "to state my position in a nutshell—given an instance of slight pelvic contraction in which the chances are against the delivery of a living child per vias naturalis, and the time for induction of premature labor with resulting viable child having elapsed, the obstetrician is justified in performing the Cæsarian section, provided always the fœtal heart sounds are clear and regular." I despair of finding better chosen words to express my own convictions and am tempted only to additionally ask whether, in such a case, he can be justified in any other procedure.

It would seem hardly necessary for me to emphasize the fact that the obstetrician alone must be the judge of what is to be done. The preference of the ignorant or prejudiced parents or of the friends, the disposition on their part to save the life of one being from any added risk at the expense of the other being, or any sentimental considerations on their part of any nature, for or against either life at the expense of the other, should not weigh at all in the obstetrician's mind or decide his course. The responsibility is his for his conduct in the case and he can not answer to his own conscience if he does that which he believes to be inadvisable or wrong, simply because someone else prefers that he should. Once let this principle obtain of permitting the parents or friends to judge and dictate what his course should be and where can we logically stop? Certainly not only when the woman has come to labor; as well should he be influenced by them at the fifth month or at the first as at the ninth. That he is justified in his action by the desire of his patient or her friends is the reasoning and excuse of the abortionist and if he is to be condemned for fulfilling such a request in the first months of pregnancy, simply because they desire it, so also is the obstetrician to be condemned for adopting a course, if he believe it to be unwise and wrong, simply because the friends or patient desire it; in neither case should their preference count as against his conviction. He should determine for himself the proper thing to do without letting sentiment or circumstance move him; should state that he will do this thing and this thing only and then either do it or give up the case. Either his firmness and conscientiousness will carry the day or someone else will be found more complacent. In either event his conscience will be clear. In no other operation, involving certainly the destruction of one human life, are men of conscience so apt to put their own trained intelligence and judgment absolutely in abeyance to the ignorant sentiment and prejudices of other people, as in that of craniotomy.

Speaking of the matter of permitting the friends or the parents to decide what should be done, Dr. E. H. Grandin says, in the *New York Medical Record*, January 6, 1891: "Should the laity have any voice in the decision whatsoever? As physicians, we are not to weigh the relative value of one life over another. We are called upon to do our best by the *two* lives committed to our charge, and if we can once deliberately conclude that the Cæsarian operation carries with it but slight if any greater risk to the woman than does embryotomy, then it at once becomes our duty to elect that operation."

View, for a moment, this operation of craniotomy in such cases as we are considering, in another light. Suppose, if you please, the mortality from Cæsarian section had been brought to 10 per cent. under proper conditions, as it has, and suppose that the operation of craniotomy upon a living child that could be delivered through the abdominal walls, had, up to this time, never been thought of, proposed or done, in what light would the man be regarded, who, while, advocating that Cæsarian section be performed in cases where from pelvic contraction or other cause, even a dead child could not be extracted through the pelvic outlet, advocating such a procedure, I say, under *such* circumstances, would to-day propose and inaugurate the up to this time unheard of and unthought of operation of craniotomy on the living child! Would his action not be regarded as monstrous and infamous? And would he not be in danger of both civil and criminal prosecution? Excepting that the operation is not a new one but has been done very many times, the conditions are such to-day as I have supposed. If we would condemn the man who would to-day inaugurate it, can we justify the man, who, it having been practiced, continues it?

Traditions are queer things. We are slaves to them in other lines than lines ecclesiastical. We have heard about, and seen, and read about and become familiar with this operation of craniotomy, and therefore it does not seem to us the horrible, awful thing it is, but if we can once bring to our mind what our horror and indignation would be if it were possible for us to be in such a position as I have just indicated (with the operation until now unheard of) we can realize to some degree what it really is. To-day I believe that practically in every case it is an unjustifiable procedure. There may be exceptions to this but certainly there can be no exceptions in our hospitals where our patients are under observation before labor, nor in our private practice where like conditions exist. Rarely, very rarely we may be called to cases where labor has progressed so far before our seeing the case that the extraction of a living child through the abdominal walls is an impossibility, and craniotomy on the after coming head is necessary. But this will be very, very seldom.

I have purposely avoided entering into the relative claims or mortality of the new Cæsarian and Porro operations. I have also avoided the whole question of whether the woman should be rendered sterile by the removal of her tubes and ovaries or the ligation of her tubes at the first operation.

---

[4] Gynecological Transactions, 1890.

The consideration of these questions or of the others which I avoided in the first words of this paper, while important, would now only befog what I have sought to make the sole question here. It is this: should craniotomy ever be done in those cases in which there can be and should be a deliberate election between it and a Cæsarian section? I vote—No.

One thing is most vividly brought to my thought by the consideration of this matter. It is the necessity for the more thorough training of medical students that they may recognize early when induced labor is likely to be required and to be successful, and when it is better to do a Cæsarian section and how to do it. They are taught to induce labor, they are taught how to do craniotomy; they are not always well taught as to how to do Cæsarian section and the Porro operation, and they are not always well taught as to when induced labor is likely to be successful, or how to recognize the cases in which they must be prepared to do, or have done, a Cæsarian section, either just before or at the onset of labor. I would not advocate that every man who is likely to attend a labor case should attempt to do Cæsarian section, neither would I advocate, did I believe craniotomy justifiable, that every man should attempt to do craniotomy. But I do believe that no man should be permitted to graduate from our medical schools, who has not such a knowledge of pelvimetry and what it means but that he shall know just what can be expected from and what must be done with every case under his care and know enough, even should he not feel competent to attempt an obstetrical operation himself, to have the services of someone for his patient who is able, not only to save *her* life, but also to deliver her of a living child.

In these days when every small city has its gynæcologist, fit and able and willing to do Cæsarian section, either at home or away from home, either for a fee or without it; when every little city has its hospital, public or private, where such an operation can be done if the patient's home is to humble for the necessities for it, there can be, in my judgment, but very rarely excuse for the sacrifice of human life made necessary by failure to recognize beforehand the conditions necessary to be met and to use the means required to overcome them.

THE TREATMENT OF POSTERIOR ROTATION OF THE OCCIPUT DURING LABOR.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY EDWARD P. DAVIS, A.M., M.D.,

Professor of Obstetrics and Diseases of Infancy in the Philadelphia Polyclinic, Clinical Lecturer on Obstetrics in Jefferson Medical College; Obstetrician to the Philadelphia Hospital, etc

Among the complications of labor not requiring surgical interference, none is more important or fraught with greater danger to child and mother than posterior rotation of the occiput. We desire to substitute this term for that commonly employed —"occipito-posterior positions"—believing that the method of obstetric study that recognizes but two positions for each presentation is more rational and serves a better purpose than the more complicated system that calls for many positions. We shall then make but two positions for each presentation. For example, a vertex presentation has a first and a second position. The first is the usual one, the back of the child directed toward the left side of the mother, and the vertex directed slightly toward the left side of the mother's pelvis. The second position of a vertex presentation is that in which the back of the child is directed toward the mother's right side, and the occiput points to the right of the mother's pelvis.

During labor the occiput, in the vast majority of cases, turns forward, toward the symphysis pubis. Occasionally it descends through the pelvis, showing a tendency to turn posteriorly, thus giving rise to what have been styled "posterior positions." It occasionally happens that during pregnancy the occiput is situated behind the centre of the mother's pelvis; whether the occiput endeavors to turn backward, or whether during pregnancy it is situated slightly behind the centre of the pelvis, it is more rational and easier of comprehension to call this abnormal turning of the occiput "posterior rotation" than to make four positions, two of them posterior. In common with many Continental students of obstetrics, we style the condition as an "abnormal rotation of the occiput," and not as "occipito-posterior positions."

The causes of the tendency to turn posteriorly are several. The mother's pelvis may be narrowed in its anterior half and its sides may lack those surfaces anteriorly to a line drawn upward and forward from the spines of the ischia that normally favor the anterior turning of the head. The head of the child may be of unusual size or contour, finding its most convenient lodgment at the posterior extremity of one of the oblique diameters of the pelvic brim. Again, during labor, the posture assumed by the mother may not be such as to favor the anterior turning of the vertex. Many cases exist in which no one factor has been found to be entirely responsible for the abnormality; thus, a small child may enter the pelvis with its head in partial extension or flexion, and this intermediate condition remaining, the occiput may turn toward the hollow of the sacrum.

Some of the symptoms of posterior rotation of the occiput may be perceived before labor has actually begun, while others are discernible only after the commencement of labor. Palpation and auscultation will often reveal the fact that the occiput is directed toward the middle line or even slightly behind the centre of the pelvic brim. The back of the child may be turned somewhat posteriorly, so that the heart-sounds seem to come from deep in one side of the mother's abdomen. If the abdominal walls are thin, the occiput can be mapped out and accurately located. If a history of previous labors be sought, there will be an account of prolonged parturition, probably ended by instrumental delivery, and often resulting in the death of the fœtus.

At the time of labor it is often difficult to map out accurately the position of the head unless the tissues be elastic and admit of manipulation. If the attending physician notices the absence of the vertex in the anterior half of the mother's pelvis, he will do well to allow her to inhale sufficient chloroform to permit the introduction into the vagina of enough of the hand to make a positive diagnosis.

We shall best understand the indications for treatment by considering briefly the course of a hypothetic case if left to nature. Statistics show that the greater number of cases result in anterior rotation of the occiput without assistance. By some the proportion of cases that rotate spontaneously to the front is placed as high as 96 per cent.; others allow but 75 per cent. My own observation and the records of 219 cases occurring at the Philadelphia Hospital, lead me to believe that 87 per cent. of these cases terminate spontaneously with anterior rotation. A source of fallacy in a study of the question arises from the fact that an exact diagnosis of the position of the head is rarely made early in labor; a practitioner is often satisfied with finding that the head is presenting and that the face is not the part found by the examining finger. Thus, a case in which posterior rotation has begun, but which terminates by turning forward, is not recognized until anterior rotation has occurred.

If we seek to ascertain the factors upon which anterior rotation depends, we find them to be essentially three in number: First, a normal proportion in size between the head and the pelvis; thus, a small head in a small pelvis favors normal rotation, and a large head in a large pelvis is likewise favorable. Secondly, a flexed position of the head is essential to anterior rotation of the occiput. Thirdly, the forces of labor must be normal, namely: the contractions of the uterus and the resistance afforded by the pelvic floor. If any one of these factors is notably deficient, a perversion of rotation is very likely to occur.

Abnormal rotation of the occiput is a source of danger to the life of the child and to the integrity of the mother's tissues, and also to her life. The child's life is jeopardized by long-continued pressure during prolonged labor, resulting in visceral hæmorrhage and death. The mother's tissues are endangered by reason of the abnormal prolongation of the pressure of the head during efforts at rotation, and her life is imperiled by the added risk of septic infection and exhaustion.

The treatment of such abnormal rotation would rationally consist in an effort to supply the one or more factors already described that may be deficient or perverted. Although the physician cannot remedy disproportion in size between the head and the pelvis, the sooner he becomes aware of such disproportion the better for his patient. No woman should be attended during her first pregnancy unless her pelvis has been measured by her medical attendant. In making this statement we do not insist upon an elaborate measurement of the pelvis, but urge that three external measurements be invariably made. These are: the external conjugate, the distance between the anterior superior iliac spines, and the distance between the outermost points of the iliac crests. If the physician has the opportunity of making such an examination as early as the thirtieth week of gestation, he may, if necessary, be able to induce labor, thus securing a normal rotation of the occiput before disproportion between the head and the pelvis has gone so far as to endanger his patient. If he does not see his patient until she is considerably advanced in labor, the knowledge that her pelvis is smaller than the average will be of great value in preventing the futile effort to deliver a large head through a pelvis too small for it. In addition to the measurement of the mother's pelvis, an effort should be made to ascertain the comparative sizes of the head and the pelvis. This can be done by placing the patient upon her back, her thighs being flexed, while the fœtal head is gently pressed downward into the pelvis by the examining hand laid broadly behind the pubes, the other hand steadying the fundus of the uterus. If more exact information is desired, one hand may be placed against the head by internal examination, while pressure is exerted with the other hand behind the pubes. A head that begins to slip into the brim of the pelvis under such manipulation is not too large to rotate successfully during labor.

Flexion of the head, necessary to secure anterior rotation, may be promoted and maintained by the employment of the hand, accompanied by the use of forceps. When the physician discovers that the occiput is turning posteriorly, while the head is but slightly flexed, if the patient be anæsthetized sufficiently to permit the introduction of the hand, the occiput may then be drawn down, or the chin pushed upward, and flexion secured. If this effort fails, flexion may be secured by axis-traction with the forceps, as will be described in a succeeding paragraph.

Flexion and anterior rotation may be further facilitated by the posture of the patient; thus, if the back of the child be turned toward the left side of the mother and the occiput tends to rotate posteriorly, the mother should be turned upon her left side, with her thighs flexed and her shoulders bent slightly forward. This posture causes the fundus of the uterus, containing the body of the fœtus, to fall toward the left side of the mother's spinal column, as it will be remembered that the uterus normally occupies a position of right lateral obliquity in the abdomen of the mother. This movement of the fundus from right to left, by gravitation, favors the turning of the occiput from left to right, and thus anterior rotation of the vertex is expedited. If the child's back is directed toward the right side of the mother and the occiput seems about turning toward the sacrum, the mother should be placed upon her right side, with her body flexed as has been described and her right side propped up from the bed by means of pillows. Gravitation of the fundus is thus favored, and anterior rotation is more likely to occur.

The posture often instinctively assumed by women, namely, that of kneeling strongly forward upon the bed, is one that favors flexion and anterior rotation. The fundus of the uterus falls forward, the head tends to flex and descend into the pelvic cavity, and the long axis of the fœtus corresponds more perfectly with the direction of the axis of the pelvis.

In addition to posture, constant external pressure against the vertex sometimes favors anterior rotation of the occiput. Thus, I remember having seen a case so treated in the wards of a foreign hospital; the patient was placed upon her side and a small bag filled with sand was laid upon the abdomen against the vertex.

We now come to consider the last of the three conditions upon which anterior rotation depends, namely, the expulsive force of the uterus and abdominal muscles, and the resistance of the pelvic floor. If the former is deficient, a suitable stimulant to the nervous system is indicated: *thus tea, coffee, alcohol and quinine* are most available; it is rarely necessary to employ ergot, and exceptionally the faradic current of electricity has been found useful. A narcotic that causes labor to cease absolutely for a time, while the patient sleeps, has often been found of value, the patient on awakening rousing to renewed activity. Direct stimulation of the uterus by rubbing the abdomen, and by pressure exerted upon the head in the axis of the pelvis, may carry to a successful parturition a labor lingering in its last stage. Again, anæsthesia of a moderate degree may temporarily remove the depressing influence of pain and cause renewed uterine activity.

While such expedients are frequently successful, yet the forceps is very often the last resource of the practitioner. In this, as in all forceps deliveries, two methods are to be distinguished. One is, that which all that use forceps desire to carry out, namely, the application of the blades accurately to the sides of the child's head; this requires a forceps modelled after French instruments, or shaped like the familiar blade devised by Davis, of London.

The other method of applying the forceps is that recognized as a valuable expedient, although not the ideal method of operating; this is the application of the forceps to the sides of the pelvis, and suggests the employment of an instrument modelled after the forceps of Simpson, of Edinburgh. In the first instance, forceps and head rotate together; in the second, the head rotates in the forceps, the blades remaining in the axis of the pelvis at the sides of its cavity. The first method requires for its safe performance a very accurate diagnosis of the precise location of the occiput; this will usually require anæsthetizing the patient and the introduction of nearly all or of the entire hand within the vagina. In the second method the occiput may not be definitely located, although its absence from its usual location may have been determined. The forceps is then applied to the sides of the pelvis, traction is made gently with the pains, and between the tractions the grasp of the forceps is relaxed, the head rotating within the forceps-blades, so that each application is virtually a new one.

Neither use of the forceps is skilful that does not at the same time employ axis-traction. All obstetricians are familiar with the simple manipulation of performing axis-traction with the hands, grasping the handles of the forceps with one hand and raising them, while the other presses downward and backward upon the instrument at the shank. If the case be a difficult one, this requires for its successful performance very considerable strength in the hands and wrists. The axis-traction forceps of Tarnier and those modelled after it represent an established method of securing axis-traction in these cases. The Tarnier instrument, however, is not convenient for the ordinary exigencies of confinement; it is too heavy, too large, and too expensive. Poullet, of Lyons, in a thesis described the application of the tapes as tractors to secure axis-traction. Many had already employed this, or a similar device, by passing a tape or cord around the shank of the forceps, and forming a loop into which the foot of the operator could rest, and by downward traction assist in the delivery. Poullet has modified and made more simple his use of the tapes, as shown in his most recent instruments. I applied the tapes, as first suggested by Poullet, to the Simpson forceps for the purpose of meeting the indications in those cases in which the occiput tends to rotate posteriorly, and in which the Simpson forceps applied to the sides of the pelvis seems most clearly indicated. The tapes have been similarly attached to the Davis forceps for cases in which that instrument seems most suitable; my experience leads me to prefer the Tarnier forceps in cases in which the instrument can be applied accurately to the sides of the head.

In using the forceps with the tapes no extra device for holding the instrument tightly upon the head is necessary. As traction is made, the tapes tend to draw the blades together; thus, in using the Simpson forceps, care should be exercised that the blades do not approach too closely.

In using either form of instrument, but moderate force is needed to effect delivery, provided axis-traction be made; the failure to perform axis-traction accounts for many of the difficult and dangerous cases of forceps delivery. The head should be kept thoroughly flexed during its exit from the genital tract; the use of axis-traction has largely done away with that function of the forceps said to favor rotation. No one would attempt to forcibly twist a vertex in the pelvis; the difference between traction in the axis of the pelvis and the attempt to deliver without such traction can never be appreciated without a practical experience with the two methods. The former is a difficult, tedious, and laborious task; the latter is a matter of much less difficulty. As illustrating the method of favoring rotation by axis-traction with the Simpson forceps the following case, reported originally in the first volume of the *Philadelphia Hospital Reports*, may be described:[1]

M. H., thirty-six years, an Irish domestic, unmarried, a unipara, was admitted to the hospital October 16, 1889, in a fairly good condition. While awaiting delivery, she suffered from numerous severe attacks of asthma, and was found to have emphysema, with some dilatation of the right ventricle. Examination of the heart revealed no valvular lesion, and examination of the urine showed an absence of albumin and of casts. For the relief of the asthma, grindelia robusta, potassium nitrite, and soda, with chloroform-inhalations, were employed. During the woman's stay in the obstetric ward her general condition did not improve, the attacks of asthma increasing in frequency, the patient becoming anæmic, irritable, and weak. About three weeks before labor, albumin in considerable amount was found in the urine, and about a week later the legs and feet became œdematous.

Labor began Tuesday, December 24, at 10:30 P.M., the patient reaching the Maternity ward at 10:30 P.M., December 25, 1889. At this time she was weak and irritable; she suffered from dyspepsia, and complained of pain in the back. The os was patulous to one finger; no presenting part could be felt, polyhydramnios being present; the uterine contractions were infrequent, of slight force, but caused great suffering. The first stage of labor lasted sixty-two hours, the general condition of things remaining much as described; the abdomen was enormously distended, tense, fluctuating; the fetal heart was distinctly heard low down in the right flank. The position of the fetus could not be made out by palpation. The patient became weaker, the pulse losing in volume and increasing in frequency to 115. At an early hour in the morning of December 28, the membranes ruptured, and a large amount of greenish liquor amnii escaped, but the head, which presented in the right occipito posterior position, prevented the escape of all. It was now found that the woman's bladder was full of urine, and catheterization was necessary. Still the head failed to descend through the pelvis, which was not markedly contracted, the measurements being: Spines, 23.5 cm.; iliac crests, 26.5 cm.; external conjugate, 18 cm.; right diagonal, 22 cm.; left diagonal, 21 cm.; trochanters 28.5 cm.; circumference, 85 cm.

The contractions of the uterus diminished in force, and at 12:30 P.M., December 28, the patient was anæsthetized with chloroform; Simpson's forceps, with the Poullet tapes attached, was applied, and the head delivered. The cord was wound twice around the neck. Delivery was difficult, consuming considerably over an hour; occiput remained posterior until just before delivery, when it quickly rotated forward. The grasp of the forceps was relaxed between the tractions to allow rotation. Double episiotomy was practiced and no considerable laceration occurred.

In bringing this paper to a conclusion, I desire first to draw attention to some errors that I think not uncommon in the treatment of these cases. Of primal importance in this report is the neglect of the effort to measure the patient's pelvis when possible, and when this is not practicable to estimate the comparative sizes of the head of the child and the mother's birth-canal. In this the profession must educate its patients, and this can be *done only if methods of examination* are conducted without exposure, without violence, and in a kindly and skilful manner. It is my custom to teach students to examine the pelvis, diagnosticate the position of the child and its presentation, and ascertain whether the head is likely to enter the pelvis readily, while the patient remains covered with one thickness of linen. We can no longer comfort ourselves with the remark that American-born women rarely have contracted pelves; this statement is not strictly true, and the large number of foreigners coming to our country show frequent examples of varying degrees of pelvic malformation. The skilful obstetrician, by his knowledge, avoids prolonged and disastrous labors, and such good results are impossible without a skilful examination of the pregnant patient. If a large head be detected at the brim of the pelvis, scarcely able to enter, and showing a disposition to rotate posteriorly, it will be found better practice in many cases to perform the conservative Cæsarean section, saving the lives of mother and child, rather than subjecting the child's life to great risks and exposing the mother to serious injury in delivery.

---

[1] Philadelphia Hospital Reports, vol. i, p. 229.

I desire, secondly, to draw attention to the efficacy of posture in favoring rotation of the occiput when the head has entered the pelvis. Whether it be that the patient lies upon the side toward which the occiput is pointing, or whether she inclines the pelvis forwards, I am convinced from observation that posture is a valuable adjunct in the conduct of such cases. I desire also to criticise that method of examination consisting in the introduction of but a portion of one or two fingers in the effort to make an accurate diagnosis of the location of the occiput, and to favor its anterior turning. The practitioner should prepare himself to apply the forceps if necessary, and then anæsthetize his patient to obstetric anæsthesia, preferable with chloroform; he should introduce so much of the hand as may be necessary to make an accurate examination of the entire vertex. In the intervals between the pains he will be able to favor anterior rotation, and when he has thus brought the vertex in front of the middle of the pelvis, without removing the hand the forceps may be applied and the labor terminated.

Third. The forceps is often applied too soon, thus neglecting one important factor in anterior rotation, namely, the resistance of the pelvic floor. If the forceps be applied before the head has had an opportunity to rotate upon the pelvic floor, its posterior turning is often favored by the instrument rather than its anterior rotation. On the other hand, the forceps is often applied too late, when flexion has become impossible by reason of the persistence of partial extension, the head becoming impacted upon the pelvic floor in this unfavorable position. The life of the child has frequently been lost in such cases before the final effort at delivery is made, and when such is the case craniotomy is often the only rational procedure.

In conclusion, I would urge the following as points of importance: First, the adoption of the simple nomenclature already stated, which has borne the test of usage on the Continent of Europe, and which will render more comprehensible the mechanism of labor. I refer to the designation of two positions only for each presentation, anterior or posterior rotation being designated, as the case may be. Second, the importance of pelvimetry and of the comparative estimation of the sizes of the head and the pelvis is paramount; by the second of these I mean the careful estimation as to the degree of engagement of the head, and if the head has not engaged, pressing it gently into the pelvis by supra-pubic pressure, the patient being, if necessary, partially anæsthetized. Third, when the head is proportionate in size to the pelvis, and lingers upon the pelvic floor by reason of failure in expulsive force, the child's life and also the mother's safety being in danger, the forceps should invariably be used with axis-traction. The forceps should be used in accordance with the possibilities of the case, and that form of instrument should be selected that was intended for such possibilities. Whenever practicable, forceps designed to be so applied should be accurately placed upon the sides of the child's head, axis-traction made, the head and the forceps rotating together anteriorly. When such accurate apposition is impossible, forceps modelled for application to the sides of the pelvis should be employed with axis-traction, the forceps making as little pressure as possible upon the head, the blades being relaxed after each traction so that rotation anteriorly may occur between the blades. Fourth, a conservative Cæsarean section may be indicated if a living child, with large, firmly ossified head, presents with a posterior rotation of the occiput, the head failing to descend into the pelvic cavity; craniotomy may be indicated if such a child has perished during its entrance into the pelvis.

THE IMPORTANCE OF SURGICAL TREATMENT FOR LACERATION OF THE CERVIX UTERI.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY AUGUSTUS P. CLARKE, A.M., M.D.,
OF CAMBRIDGE, MASS.

The opportunities now afforded to the gynecologist for studying the effect in any case of laceration of the cervix uteri leave but little doubt that treatment is a most important subject for consideration. Experience has, however, demonstrated that the local application of the various agents which from time to time have been suggested as being remedial or beneficial is at best but a temporary expedient. Whenever a laceration occurring at the cervix extends through the internal and external muscular tissue, the mucous coat lining the canal suffers materially from the violence. The plicæ palmatæ which have been described under the term arbor-vitæ undergo serious disturbance in their relation to the other tissues with which they are connected. This condition often leads to congestion, thickening and to induration of the parts involved and to more or less hypertrophy and malnutrition of the higher uterine segments, and to changed relation and to displacement of the lower cervical zone. When laceration occurs at the cervix it is not only that the muscular and the mucous structures are injured but it is also that the mucous glands which so freely abound in the uterine canal become disturbed in their normal functional activity. It is especially the cervix uteri about the arbor vitæ that the mucous follicles which when in a healthy condition afford only a moisture for the maintaining of their function, give rise to the formation of an altered, perverted or diseased secretion. The arteries and arterials entering into these structures often become preternaturally developed or enlarged; there will often be found a greater interlacing or anastomosing of these vascular structures. This condition may lead to more or less local œdema, which the venules and lymphatics will fail to overcome. The structure of the uterine nerves, particularly those derived from the hypogastric and sacral plexuses, become so deeply involved that not only the parts in immediate contact with the torn or injured surfaces become the source of much trouble but all the tissues forming the uterine body may continue so heavily congested and become so thickened, indurated and globular as to be recognized only as that condition which has so aptly been termed, subinvolution of the uterus.

The treatment best adopted for the relief of the suffering which occurs in every such case, according to my experience, is that afforded by surgical measures. The history of the following case illustrates in some measure the importance of such treatment.

Mrs. C., aged thirty-six years, descended from good stock, and was originally of sound constitution and in good health. Her embonpoint, though fair, was not excessive. She was a sextipara. The eldest child was eleven years old and the youngest three years. At the time I was first called, Dec. 14, 1891, there had been a most profuse uterine hæmorrhage. On my arrival I found that the patient was blanched; her pulse exceedingly weak and easily compressible. The cardiac sounds were feeble and gave indication that there was some dilatation and perhaps fatty degeneration of that organ. The patient had, for the most part, been regular in her catamenial flow, though she had suffered at times from unusual loss of blood. There was no evidence in the history of the case to show that the patient was suffering from the effects of abortion or that she was pregnant, or at any time had ever suffered from a miscarriage. A few days immediately preceding the date of my attendance she had been doing some extra household work and had attempted to lift some heavy articles of furniture. This may have been the exciting cause of the hæmorrhage. Vaginal examination revealed that the cervix was patulous, that it was hard and unyielding, and that multiple cervical laceration had evidently long existed. There was also an old perineal laceration which might have contributed somewhat to her inconvenience. By tamponading with iodoform gauze, the hæmorrhage was brought under immediate control. Next day a thorough vaginal examination showed that there was subinvolution; the depth of the uterine cavity was six and a half inches; there was also cicatricial ectropium of the cervix to an unusual degree. For some days the use of the tampons was continued, though there was no further hæmorrhage. The patient subsequently suffered severely from facial and super-orbital neuralgia, sometimes on the left side, and at other times on the right. The patient also suffered from sciatica appearing on the right side; the occurrence of this affection had, from time to time, heretofore added much to her illness. Full and repeated doses of morphia and of other opiates often afforded her marked relief; stimulants were well borne and were frequently required to overcome the narcotic effect of the soporifics.

Dec. 22.—The patient suffered from a severe attack of gastralgia, which yielded only to morphia hypodermatically administered. Under careful regulation of diet, and with the judicious use of stimulants the patient from this time forward gradually improved, though she was kept in bed in consequence of the local inconvenience from which she suffered every time she stood or was in the erect position.

Feb. 3.—With the assistance of Dr. A. H. Tuttle, the patient was etherized and placed on the table for surgical treatment. All details of the operation were carried on under strict antiseptic precautions. The uterine cavity still measured six and one half inches. This was first curetted; after this the cervix was repaired. Aseptic animal sutures were employed. The mucous tissue of the lacerated perineum was then dissected up as far as the sulcus on each side; coaptation of the torn surfaces of the perineal tissue was effected by the employment of the same kind of aseptic animal suture. The deep sutures were first inserted; each tissue was brought together in its proper order, last of all the edges were brought together by the buried suture and the parts united were sealed with collodium and iodoform. The whole was protected by dressings to the cervical, vaginal and perineal tissues. The patient rallied well from the ether, though more than the average quantity had to be used to overcome all rigidity of the genital tract. The bladder was catheterized at regular intervals to prevent the repaired tissues from becoming contaminated by the discharge of the urine. The patient suffered very little from the effects of the operation; there was no increase of temperature. She experienced some trouble from a return of sciatica, though this occurred on the left instead of the right side. Neuralgia occurring in the face and in other parts was at intervals complained of. She took nourishment and stimulants freely until the evening of the twelfth of February, when she began to suffer from dyspnœa; the pulse at that time became irregular, and the heart's action at intervals was labored. Though the patient was able to continue the use of nourishment and stimulants she died during the evening of the fourteenth. Autopsy twelve hours after death.

On opening the chest the heart was found to have undergone more or less fatty degeneration; both ventricles were somewhat dilated. The left ventricle contained an antemortem clot. The lungs were congested. The liver gave indication that it was undergoing also fatty degeneration; the spleen, however, was normal. The right kidney was congested and was darker than normal; the left one showed that marked organic changes had for some time been going on, and that it was approaching to a condition of parenchymatous inflammation. At the cervix uteri, where the lacerated tissue had been brought together by the operation for repair, the parts were in a healthy condition; the line of union had nearly healed. The uterine canal also presented a healthy surface; it showed that all the fungoid granulations had been removed by the curetting. The uterus showed that there had taken place a rapid retrograde metamorphosis of tissue, for the canal itself measured now scarcely four inches in depth. There had already taken place a strong line of union at the coapted parts in the torn perineum. There was no indication, about the parts, that any sepsis had occurred. The autopsy, which had been carefully conducted, did not give the slightest indication that there had been any septicæmia or that other morbid process had occurred as the result of the surgical measures undertaken for the patient's relief. The autopsy further showed that there was no pelvic or uterine tumor and nothing to indicate the existence of a cancerous development, though such had been believed to have existed by some of her previous medical advisors.

In view of all the facts connected with the case it seems fair to conclude that the cause of the death was owing to the excessive loss of blood which occurred immediately previous to my first visit. This loss of blood necessitating the horizontal position which had to be so long assumed must have hastened the degenerative changes that had before been insidiously developing. It is also fair to infer that had the operation for her relief been instituted before the lapse of so many years, during which she had suffered from hæmorrhage and from other untoward symptoms, her life might have continued a much longer duration. In another case of cervical laceration occurring during labor the patient suffered much from endocervicitis and from uterine hæmorrhage. After coming under my care she had intended to submit to an operation but had delayed the matter owing to a succession of cases of illness that appeared in her family. The patient suffered much from the subinvolution and from the local inconvenience whenever she travelled or was about her house. She had grown stout, but her flesh was soft from a lax habit of the body. Auscultation revealed that though there was no distinct cardiac murmur the two sounds were weak and that dilatation and fatty degeneration had begun to take place. Another severe uterine hæmorrhage so prostrated her that she had to be confined for some weeks to her bed. She suddenly died from degenerative changes occurring in the cardiac tissue. In this case there can be no doubt that had surgical measures been adopted for her relief before she had sustained so much loss of blood, the fatty degeneration of the heart's structure would not have been accelerated by the influences of the recumbent position which she also, from time to time, was frequently enforced to take. In cases in which the disturbance is greatest at the cervix uteri operation for repair will often yield most favorable results. In such cases it is surprising to see how speedily the thick and indurated tissue at the cervix softens and relaxes under the influence of the stimulus imparted by operative interference. The venules and lymph vessels which seemingly, had long since lost or suspended their function, take on an almost immediately, for effecting this accomplishment, renewed activity. In a case of cervical laceration to which I was recently called, there was but little that could be expected to be achieved by the adoption of surgical measures on account of the unusual hypertrophy of the tissues, which had taken place, and also on account of the exhausted condition of the patient. The operation however, was undertaken. I was happily surprised to find that I had succeeded in effecting so much toward the reduction of the induration and toward bringing about restoration of the cervix. In cases of cervical laceration before the structures become indurated or cicatrized the ectropium or eversion of the tissues of the os uteri may be the chief indication for which surgical treatment is required. Eversion, when present to any great extent, almost always gives rise to much local suffering, especially whenever the patient assumes the erect position. Such a condition of the cervix is sometimes the cause of sterility; it often interrupts the marital relation. In a case to which I was called in consultation some two and a half years ago the tissues of the os uteri so projected forward as to give the impression to the medical attendant, when the examination was made without the help of the speculum, that a fœtus at the term of four months or more, had engaged the cervical canal. This patient had been the mother of four children, during the birth of the last of which laceration of the cervix occurred. As a consequence of this injury, repeated hæmorrhage had been a troublesome factor; this had often come on without apparent connection with the influence of the catamenial flow. This case under temporizing treatment had dragged on for upwards of three years. A resort to trachelorrhaphy was followed with marked amelioration. Emmet, as it is well known, long since expressed his belief that nearly all cases of uterine epithelioma or cauliflower growth have their exciting cause or origin in laceration of the cervix uteri. The cancerous development according to Emmet, arises from prevented nutrition in nature's attempt to repair the injury.

Professor Graily Hewitt, of London, and other eminent authors have expressed their opinion that injury to the cervix by labor, is the predisposing cause of uterine cancer. In a case which has recently come under my care the history showed that there had been a cervical laceration dating back some ten years. The patient's age was forty-six years; she was a multipara. There had been considerable induration and eversion. Nothing from the history could be learned that cancer had ever appeared in her family. The patient, for several months previous to the manifestation of cancer in the cervix uteri, had dwelt in a family in which two cases of cancerous disease had occurred. In another case to which I was called, the patient was a primipara; her age was twenty-nine years. There was no evidence that malignant disease in either branch of her family was hereditary or that in either of them a case of such disease had ever appeared. One year before she had experienced the initial symptoms of cancer of the cervix she had devoted much time in the care of a friend who was suffering from cancer of the breast. She had incurred a cervical laceration during the labor which took place five years before. She experienced considerable inconvenience from the effects of the laceration, and had from time to time received local treatment; no operation, however, for repair of the cervix was ever undertaken. In many cases of laceration of the cervix induration that takes place is limited to an exceedingly small section; the eversion may give but little trouble. In such cases there may have been no arrest of the action of the absorbents that are engaged in the removal of the provisional material incident to pregnancy. In some cases of this class, it would seem that the occurrence of laceration increases the activity of the absorbents, or at least helps to expose them to the agency of the materies morbi or to that of the disease germs, which at any time may gain admission into the vaginal introitus. As more evidence has of late been adduced tending to show that cancer in its various manifestations is a contagious[1] affection a much stronger plea than heretofore, can now be offered in support of the advantages to be derived by the resort to the operation for repair of the cervix in which laceration has occurred, though it be of a minor grade.

THE MANAGEMENT OF CANCER OF THE UTERUS, COMPLICATED BY PREGNANCY, WITH REPORT OF A CASE.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual meeting of the American Medical Association, held at Detroit, June, 1892.

BY A. VANDER VEER, M.D.,

PROFESSOR OF DIDACTIC, ABDOMINAL AND CLINICAL SURGERY, ALBANY MEDICAL COLLEGE, ALBANY, N. Y.

Pregnancy and uterine cancer are conditions, fortunately, rarely associated. Winckel saw eight cases of cancer of the cervix uteri in a total of fifteen thousand cases of pregnancy. Stratz saw twelve in seventeen thousand nine hundred cases. Sutugin saw two in nine thousand, or, in other words, out of nearly forty-two thousand cases of pregnancies, observed in three great obstetric clinics, only twenty-two cases of cancer of the uterus occurred as a complication, roughly, one case in every two thousand cases of pregnancy. Like all statistics these have only a relative value. Consulting obstetricians see relatively more cases than do general practitioners, and apparently see as diverse results of treatment. For example, the much-to-be-lamented late Dr. Fordyce Barker reports, in a discussion, three cases which were delivered, without any unusual complications, of living children at term, the mothers also recovering from childbed without serious drawbacks. Other obstetricians of equal skill have seen this complication followed time after time by death of the mother, undelivered. Naturally, from their own experiences, these gentlemen cannot come very closely together in discussing methods of treatment.

---

[1] Observations of M. Guelliot and M. Arnaudet. *L' Union Medicale, 1891.*

If we take a wider view of cancer of the uterus and pregnancy, with regard to the mother, out of twenty-seven cases seen by Puchett, five died during labor undelivered, nine shortly after delivery, ten recovered from the effects of labor, and in three the results are not stated. Leaving out of consideration the three cases in which the results were not known, we have a maternal mortality, from the delivery, of fifty-eight per cent. plus.

Cohnstein in another considerable series of cases, where gestation was completed before labor occurred, found an average maternal mortality of 57 per cent. Hermann out of one hundred and eighty cases found a maternal mortality of 40 per cent., and that 20 per cent. of these died before delivery took place. To consider the subject more accurately, from this large number of cases, out of nearly three hundred women suffering from cancer of the uterus, and in labor at the end of gestation, 52 per cent. died undelivered or never left their beds. Hermann also showed a maternal mortality of 31 per cent. where the labor was practically normal. According to Gusserau and Cohnstein, abortion or premature labor occurs in 35 per cent. of pregnant women with cancer of the uterus. The maternal mortality is not materially lessened by abortion and premature delivery. If we go a little farther in our analysis of this frightful mortality, we find, first of all, that 25 per cent. died undelivered from septic infection brought about by a putrid fœtus or from shock and exhaustion. Sepsis after delivery of the fœtus, from absorption through large areas of unhealthy and non-cicatrizing granulations, or from retained placenta, is responsible for another large proportion of the deaths. Post partum hæmorrhage another portion, and rupture of the uterus still another. Yet with all these dangers menacing the mother's life, by this complication of pregnancy, we still have another, i.e., the stimulus of unusual uterine blood supply to the cancerous mass, encouraging rapid cell proliferation and infiltration of the vagina, broad ligaments and rectum. Finally, few of the majority who survive the ordeal of delivery live three months.

For the children are the conditions less favorable? Of the above series of cases only 33 per cent. were born living, and hardly 20 per cent. lived until the mother left the childbed. Here then we have 20 per cent. of living children at the threshold of their existence and over half without mothers.

I know of no condition of disease that presents a darker or sadder image than does this one. An image rarely seen to be sure, yet none the less frightful, an image that has not, it is to be feared, received the attention in text-books and from teachers of obstetrics and medicine that its moment deserves. I have tried to outline fairly the course that cancer of the uterus, when complicated with pregnancy, has taken in the past, in order that we may come to a clearer conception of our duty to these cases in the future. If the foregoing shows anything, to my mind, it shows that we cannot afford to wait for emergencies, delivery, abortion, and septic infection to arise, if we ever expect to reduce the mortality of this dreaded condition.

If the gentlemen of this Section were called upon to state their individual preference for the treatment of operative cases of cancer of the cervix uteri in two words, I am confident that the larger number of replies would be vaginal hysterectomy, rather than high amputation, total extirpation, or partial excision. It is pertinent to ask why shall the principles of treatment be modified because pregnancy exists? I hold that unless exceptional circumstances are present that total extirpation should be the rule, and the operation should be done at the earliest moment.

Cases of cancer of the cervix uteri, associated with pregnancy, so far as treatment is concerned, may be classified in three series.

1. Cases where the disease is confined to the uterine tissue, no infiltration in vagina, bladder, rectum or broad ligaments, and the uterus has not reached a size incompatible with vaginal hysterectomy, say up to the end of the fourth month of pregnancy.

2. This series comprises all cases presenting the features of the first series, except that the removal of the uterus by vaginal hysterectomy, because of the late period of gestation, after the beginning of the fifth month, is precluded.

3. This series comprises all cases at any period of gestation where total extirpation of the uterus is impracticable.

In the management of the first class of cases, associated with early pregnancy, abortion, either accidental or induced, has already been shown to be surrounded by many dangers, and notwithstanding its successful employment by a few operators, as a preliminary to vaginal hysterectomy, it is not a procedure to be recommended.

High amputation of the cervix in these cases, in the majority, brings about abortion and its attendant dangers, and is even less successful than in the non-puerperal uterus, in regard to final cure.

Allow me to illustrate to you by the following case from my own practice the management of a case of the first group:

Mrs. A. H., aged 27 years, native of United States, housewife by occupation. Referred to me by Dr. A. V. H. Smythe, of Amsterdam, N. Y. Admitted into Albany Hospital Sept. 23, 1890.

Family history: mother died in childbirth; father, brother and three sisters living and in good health. Personal history: menstruated at the age of 13; married at 15; first child born ten years ago, second seven, and third five years ago, with one miscarriage between second and third child. About one year ago patient noticed some abnormal condition of menstruation, in that it was more frequent and profuse. This condition has constantly grown worse. Has had a very intelligent line of treatment given her, but without relief. Has some lancinating pain through pelvis, has lost in flesh, is anæmic, does not rest well, appetite feeble and realizes that she is gradually growing weaker. About two and one half months ago she was confined to her bed for three weeks, owing to her great exhaustion. Patient has always done hard, manual work, and connects her trouble with the especially severe tax upon her strength. Dr. Smythe sent her to me with the diagnosis of carcinoma of the cervix. He tried, and made various applications to the growth, but without any substantial control of the hæmorrhage, and with a constantly increasing development of the disease.

On examination I found a cauliflower-like excrescence protruding very uniformly from the anterior two-thirds of the cervix, coming out, as it were, from a bi-lateral laceration, not particularly sensitive to the touch, but having a hard, indurated base. Pelvis apparently in a healthy con dition, and no infiltration of the vaginal walls. She stated that for the past three months she had flowed almost constantly, accompanied by a very nasty odor. Bi-manual examination disclosed a uniform enlargement of the body of the uterus, to the size of a small orange, and believed to be an advance of the disease to the fundus. When asked as to the possibility of her being pregnant she did not think it possible. Was not nauseated in the same manner as with her other children, had no pain in her breasts, nor in any way did she have the symptoms of her previous pregnancies. I felt that I was justified in endorsing the doctor's diagnosis, with the possibility of her being pregnant, and recommended most earnestly a vaginal hysterectomy. This the patient, on explanation, was anxious to have done, in which conclusion her husband readily consented.

Operation was performed September 30, 1890. Was in no way complicated until I had liberated the uterus quite entirely when I found it was even somewhat larger than I had mapped out in the previous bi-manual examination. On examining the specimen after removal, the whole cervix was found implicated in the growth, and the body of the uterus contained a fœtus of about two and one-half months; ovaries and appendages were not removed. Patient made an uninterrupted recovery with the exception of an abscess that formed somewhere in the stump and was detected October 2, opened, and glass drainage tube introduced, parts thoroughly washed, some slough removed; discharge quite offensive for two or three days, when she went on to a rapid recovery.

I cannot but believe that the sloughs and the offensive discharge were the result of the use of the forceps, the latter being used instead of ligatures in the operation. This patient has remained in perfect health since her recovery, is able to do her housework, is bright and cheerful, and in every way quite happy; husband is loyal and contented.

The specimen was referred to Dr. W. G. MacDonald who has kindly furnished me with the following microscopical report. I wish also to state here that I am greatly indebted to him for the statistics contained in this paper.

"The specimen furnished for examination was a pregnant uterus removed with its contents by vaginal hysterectomy. An incision in the long axis showed the uterine contents. The entire preparation had been hardened in alcohol. The entire cervix is envolved in tissue distinctly harder than normal. The os uteri and inferior portion of the cervix is completely replaced by a soft, spongy growth resembling cauliflower. Portions of this growth were further hardened, stained and examined. The sections presented a distinct alveolar, or, more accurately, tubular structure, with abundant small-celled infiltration, especially in the periphery of the growth. With higher amplifications these alveoli or tubules show that they are closely packed with epithelial elements, chiefly columnar in character. The cellular infiltration resembles closely that seen in scirrhus of the breast. From the foregoing the pathological diagnosis is that of adeno-carcinoma of the cervix uteri."

The points of interest in this operation seem to be as follows: She had irregular menstruation, hæmorrhage, as it were, for over a year, yet when the disease must have been pretty well advanced she became pregnant. Was this a case in which the fœtus would have gone on to full time and could then have been delivered by abdominal section, and what would have been her chances as regards the development of the growth? Would it not have placed her among the hopeless cases, with the vaginal walls implicated and the pelvic glands also infiltrated? I would not hesitate in recommending the same line of treatment to another patient similarly situated. The favorable termination of this case has been especially gratifying to me. From the history of the case, and other similar ones operated upon, it will be seen that one of the chief difficulties lies in the uncertainty of diagnosis. An absolute diagnosis of pregnancy can be made in only very exceptional cases before the fourth month, when the condition complicates pregnancy. Before that time the uterine enlargement will most often be attributed to invasion of the fundus by the new growth.

The technique of the operation, owing to a degree of laxity of the tissues associated with pregnancy, is not made seriously embarrassing.

Antro- or retroversion of the uterus may be made either difficult or impossible in consequence of the volume of the uterus. The placing of ligatures on the broad ligaments may be impossible before the removal of the uterus from lack of room, but clamps may be employed either temporarily or permanently. Greig Smith, who always employs clamps, thinks that the operation is made easier when complicated by an early pregnancy.

There have been, including this one, sixteen cases of vaginal hysterectomies for cancer of the cervix uteri, complicated by an early pregnancy, *i. e.*, before the end of the fourth month, in which the mortality is *nil*. These operations have been distributed among a large number of operators, Landau, Kaltenbach, Hofmeier, J. Greig Smith, Taylor, Korn, Jonas, Mary A. Smith and others. Jonas employed a modification in first inducing abortion, and in a few days proceeding to hysterectomy, but complications reported by him, and reasons already given, do not encourage this method of practice.

The management of the second series, operative cases of cancer where pregnancy has so far advanced that vaginal hysterectomy is precluded, by the volume of the uterus, presents many problems for our consideration. Some of these present peculiar features in individual cases. For example, a woman with no living children presents herself for treatment at the end of the seventh month of gestation, for cancer of the cervix uteri. She is anxious to have a living child. Shall we follow the rule of surgery, cancer once diagnosticated, immediate operation, or shall we wait, keeping the case under observation, until gestation is completed? Knowing the rapidity with which carcinoma infiltrates, under the stimulus of pregnancy, delay may place the mother beyond relief. Operation destroys the child. Undoubtedly some of these cases may be safely tided over until delivery per vaginum can be accomplished or a Porro operation done at term, followed by extirpation of the stump.

The management of carcinoma of the cervix, associated with late pregnancy, after viability, and where the new growth is rapidly proliferating, will require, as a rule, the total extirpation of the uterus, by the method of Freund, as modified by Tweifel. First, a Porro operation, treating the pedicle by an elastic ligature and dropping it, to be followed by an immediate vaginal extirpation of the stump. Here, perhaps, the early operation may prejudice the chances of living in the child, but they certainly increase very materially the chances of ultimate recovery of the mother.

The third group of cases of cancer of the uterus, inoperable ones, will necessarily be seen very infrequently. Here more latitude may be allowed and the interests of the mother may be sacrificed in a degree for those of the child. Seldom will active interference be demanded unless from feebleness of the fœtal heart sound, or feeble movements showing that the fœtus is not doing well. At term the chances of delivery of a living child should be carefully considered, either naturally or by the aid of forceps. When delivery presents great difficulties, or seems impossible, the Porro operation seems indicated above all others, and may present advantages even if the child is dead.

Briefly the treatment of carcinoma of the uterus may be summarized as follows:

In all operable cases where the pregnancy is not advanced beyond the fourth month, do a vaginal hysterectomy at once. In all operable cases between the fourth month and term, as a rule, complete extirpation of the uterus by Freund's method, as modified by Tweifel, and in inoperable cases delivery at term or a supravaginal hysterectomy of the pregnant uterus, Porro's operation.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Section on Orthopædic Surgery.

Stated Meeting May 20, 1892.

Henry Ling Taylor, M.D., Chairman.

CONGENITAL DISLOCATION OF BOTH PATELLÆ.

Dr. S. Ketch presented a little girl who, at first glance, seemed to have only knock-knee, but on flexing the limbs, a complete dislocation of the patella downwards and forwards was observed, and the dislocation could be readily reduced by extending the limb. The deformity was much more marked on the right side. The condition was probably congenital, although it had not been noticed by the mother until recently, as the child was able to walk with no more difficulty than is observed in an ordinary case of knock-knee. Dr. Shaffer had suggested that this was the opposite of the condition which he had described under the head of Elongation of the ligamentum patellæ at the last meeting of the American Orthopedic Association.

Dr. John Ridlon said that he had seen three such cases in the practice of the late Dr. Thomas. The treatment had consisted in hammering the deficient condyle with an egg-shaped wooden mallet, and in two of the cases, the treatment had already effected sufficient development to prevent dislocation, and in the other case the treatment had only been just begun.

Dr. W. R. Townsend said that he had presented some time ago to the Surgical Section of the Academy of Medicine a colored girl who could, by muscular action, produce at will a complete dislocation of both patellæ, either to the outer or the inner side. A knee-cap was applied, and an effort made to restrict the movements of the fibres of the vastus externus and internus which seemed to be abnormally developed. She was kept under observation for six or eight months, and at the end of this time, she could not produce the dislocation at will, and the dislocation occurred quite infrequently.

Dr. N. M. Shaffer said that in his case of elongated ligamentum patellæ, the man had had a fall, which was followed by an outward dislocation of the patella on the right side. After consultation with several other surgeons, in view of the fact that the inter-condyloid notch was filled by an exostosis, it was considered best to make no attempt at reduction, and at present, although the patella lies on the outer aspect of the joint, the man is perfectly able to walk ten or fifteen miles a day. In the case just presented, he did not think the external condyle was deficient, but the ligamentum patellæ was so short that the patella, instead of passing over the trochlea, is drawn down to a point where, owing to the knock-knee, it is very easily dislocated. On this account, he thought that treatment directed towards securing an elongation of the ligament would be more apt to prove successful, than simply hammering the outer condyle.

Dr. Ketch in closing the discussion, said that he agreed with the last speaker as to the inadvisability of resorting to operative measures. Not long ago he had seen a young lady with a somewhat similar condition. Twelve years before the patella had been dislocated by muscular action, and this had again occurred shortly before he saw her. Reduction was easily affected by extending the limb.

Dr. Royal Whitman presented several patients.

Case 1.—A girl, fourteen years of age, to illustrate the appearances in non-deforming club foot. As in many similar cases, the history was one of awkwardness in walking for many years, with increased pain and discomfort during the past six months. She presented the calluses on the balls of the feet, the contraction and tenderness of the plantar fascia, and the limitation of dorsal flexion to which Dr. Shaffer had called attention in his original communication.

Case 2.—A woman, fifty-seven years of age, who had suffered from chronic rheumatism for many years. On the left side the contraction of the plantar fascia had thrown the foot into a position of equino-varus. There was no deformity of the right foot, but on both sides, a well marked limitation of dorsal flexion. The electrical reactions were normal. The condition was similar to non-deforming club foot, and was apparently the result of a rheumatic inflammation.

Case 3.—A girl of fourteen, with marked spasmodic flat foot. The case was presented to illustrate the extreme and progressive deformity and disability in this class of cases which could be easily and quickly relieved by the method of treatment to which he had on several occasions called the attention of the Society.

Case 4.—A girl of eighteen with persistent abduction of the right foot. Although there was no evident deformity, the foot was held in an abducted position by spasm of the peronei and extensor longus digitorum muscles. The condition was the result of a slight sprain three months before. The symptoms were pain, fatigue and insecurity in walking. The case illustrated the condition in so-called chronic sprain of the ankle, which practically never recovered. because the foot being unbalanced by irregular muscular action, was constantly subjected to injury. When the condition was recognized, a cure could easily be accomplished by restoring the normal muscular action. The patient being etherized, the foot should be forced into a position of extreme equino-varus. All adhesions were thus broken up, and the contracted muscles were stretched. The foot was then placed in plaster of Paris, and later, by massage, exercises, and a temporary support, the patient could be completely and permanently cured.

Dr. R. H. Sayre thought that in the fourth case there might have been a fracture of the lower part of the fibula, complicating the sprain, which had been overlooked in the treatment of the case immediately after the injury.

Dr. Ketch thought that the fourth case gave evidence of a possible osteitis about the ankle joint, and this condition should be carefully excluded before adopting the treatment proposed.

Dr. Whitman said that he found no indications of an osteitis in the fourth case, and that there was no history or present indication of fracture complicating the original sprain.

Dr. Shaffer said of the second case, that the exaggerated extension of the toes, and the shortened plantar tissues were characteristic of non-deforming club foot. He had seen several cases where the symptoms had not become prominent until the age of thirty-five or forty years was reached, and then, whether there was a rheumatic diathesis or not, all the symptoms would be greatly exaggerated. Many cases showed much less deformity than that exhibited in

Dr. Whitman's case. The typical non-deforming club foot showed little or no deformity as such, unless it was sought for and found in the shortened plantar and post-tibial tissues. The lack of proper length prevents normal antero-posterior movement at the ankle, and in the tarsal joints, and the entire weight of the body falls upon the "ball of the foot" in locomotion. It is far more common than is generally supposed, and with the use of the antero-posterior traction shoe, there is no necessity whatever for a division of the resisting tissues.

Dr. R. H. Sayre thought the second case presented very much the condition found in ordinary cases of chronic gout and rheumatism, and he had noticed that after the foot had been manipulated somewhat, she was able to move it much better than before, and could voluntarily flex the ankle beyond a right angle, so that it did not seem to be a case of non-deforming club foot.

ANKYLOSIS OF THE HIP.

Dr. Irving S. Haynes, present by invitation, exhibited a specimen of this condition, which he had found in the dissecting room of the University Medical College. The subject was a man about twenty-five or thirty years of age. The limb was slightly flexed, abducted, and rotated inwards. A sinus opened about half an inch below Poupart's ligament, and one inch internal to the anterior superior spinous process. It passed backwards, soon divided into two tracts, one leading down to the front of the great trochanter, the other up under Poupart's ligament into the iliacus, and then into the obturator internus muscles; then around the middle of the outer border of the obturator foramen into the cotyloid notch, and so into the hip joint. The iliacus and obturator muscles, as well as all the muscles acting upon the hip joint had undergone extensive absorption, and fibrous degeneration. The center of the disease, and the starting point, seemed to have been in the head of the femur, but there was also a focus in the epiphyseal line of the great trochanter, which communicated with that found in the head of the femur by a sinus running through the neck, and also opened in front through one or two small openings. Another sinus seemed to have led from the acetabulum through the cancellous portion of the ilium into the iliac fossa, where the opening was surrounded by bony formations. Between the ilium and sacrum there was slight mobility of a gliding nature, which the speaker had never observed before, and which was probably intended to partially compensate for the lack of motion at the hip. There was no evidence of the disease in the capsule of the joint. The abscess cavities were limited to the absorbed portions of the iliacus and obturator internus muscles.

ARTHRITIS DEFORMANS.

Dr. Haynes also exhibited a specimen of this condition, showing erosion and reproduction of bone, with a depression in the acetabulum, and a disappearance of the ligamentum teres. The motions of the joint were slightly limited in every direction. The specimen was removed from an old subject.

THE TREATMENT OF LARGE ABSCESSES IN POTT'S DISEASE.

Dr. W. O. Plimpton presented several cases of Pott's disease with large abscesses as an illustration of the treatment which he advocated. He did not favor aspiration, because he thought after this had been done, the abscesses were likely to continue to enlarge and burrow into the tissues. While admitting that abscesses were not infrequently absorbed, he wished to deprecate the let-alone treatment of large abscesses which tend to burrow deeply into the tissues, threatening to inoculate these tissues, often causing mechanical deformities of other parts.

The first case was a boy about 12 years of age, who had had Pott's disease since he was 3 years old. The disease followed closely upon a blow from a brick. When he first came under the speaker's care last July, he was very anæmic and weak, with an afternoon rise of temperature. There was a very large abscess situated beneath the glutei muscles, and there was much deformity of the leg, viz.: apparent shortening, inward rotation, and adduction, caused by the abscess. Free incision evacuated a large quantity of fluid, together with broken down tissue. An examination with the finger showed no involvement of the joint. The diseased parts were thoroughly curetted with a Volkmann spoon, a counter-opening made and three drainage tubes inserted. After washing out the cavity with a weak bichloride solution, the superficial cavity was obliterated as far as possible by means of sutures, and primary union occurred except at the site of the drainage tubes. Two of the tubes were gradually withdrawn. The third one, in front, still remains in for drainage, although it has been considerably shortened. The apparent inequality in the length of the limbs has disappeared since the operation, and with a plaster jacket to support the spine, he is able to go to school, and to play with other children. The discharge is steadily becoming less.

The second case was a girl, 7 years old, whose disease dates back to a fall about three years ago. When first seen one year ago last January, there was a moderately large abscess, which was opened, and a tube 6 or 8 inches long inserted. The tube has been gradually shortened until it is now 3 inches long; the discharge is diminishing, and the patient's general health has markedly improved. Another case was treated in a similar manner, and has steadily improved since the operation. In all, there had been a gradual reduction of the temperature after the operation. The same precautions are observed as in any cutting operation where it is the intention of the surgeon to secure primary union, and after the operation, care was taken to keep the wound and dressings aseptic.

Dr. W. R. Townsend said that the location of the tube in the first case reminded him of an accident which occurred about one year ago. He was hastily summoned to the hospital on account of one of the patient's having a hæmorrhage. He found that a case of large psoas abscess which had been opened and a drainage tube inserted, three weeks before, had suddenly begun to bleed profusely. The hæmorrhage was arterial, and with the assistance of Dr. W. T. Bull, he cut down and found that the pressure of the drainage tube had caused a large perforation in the femoral artery. He accordingly tied the artery above and below the perforation, and the child recovered without further accident.

Dr. Ketch thought the cases presented very much the appearance of those which he had seen in the hospital when it was the rule to open all abscesses as soon as the abscess approached the surface. They did not seem to him to differ materially in their course from those where the abscess was allowed to open spontaneously, and he could not see that anything had been gained by this method of treatment.

Dr. Ridlon asked if the drainage tube had been left in for so long a time for fear that the opening would close up, and necessitate another operation. He had always thought that it was not necessary to leave in the tube more than a few days.

Dr. A. M. Phelps thought that the second case had had decided advantage over the first in being subjected to the operation at a much earlier stage. The slightest increase in an abscess, in his opinion, warranted prompt incision. He spoke emphatically because the Section had almost been committed to the idea that it was better for these abscesses to take care of themselves. But it must not be forgotten that these abscesses were originally collections of tuberculous material and that when they become infected with pyogenic germs, as almost inevitably occurs, there will be a rapid burrowing of the pus. Another reason for opening these abscesses is that they exert an injurious effect by the internal pressure of the exudate upon the carious foci in the diseased vertebræ, keeping them bathed constantly, and furnishing a fertile source of the subsequent breaking down of these vertebræ, and of a consequent increase in the deformity.

Dr. Ketch thought that the previous speaker had not correctly stated the position of the Section on this subject. He thought it would be more correct to say that they took the ground that so many of these abscesses disappeared spontaneously under proper mechanical treatment, that something more than mere accident was necessary to explain it, and that these collections of pus cause injurious pressure had not been proven. The proof of this would be found in a marked increase in the size of the deformity, but in disease of the dorso-lumbar spine, where these abscesses were the most frequent, this did not occur, and Dr. Myers had recently presented a boy who had had two large iliac abscesses disappear spontaneously, and yet there had been no increase in the kyphos, as shown by repeated and careful tracings.

Dr. Shaffer said that extensive observation had taught him that with efficient mechanical treatment, the abscesses of Pott's disease almost uniformly pursue a benign course, and he believed that the time would come when those who now operate will see their error. He had seen in the practice of some of the best surgeons in this city, deaths occur after operating upon just such abscesses. When an abscess is very tense, and there are severe local or constitutional symptoms, all recognize the propriety of incision, but ordinarily, these abscesses are flaccid, and do not cause any such "damming up" and injurious pressure as had been described by Dr. Phelps.

Dr. Whitman could see no good reason for waiting until the abscesses appeared below Poupart's ligament. When first discovered, they should be aspirated, and if this fails, iodoform emulsion should be injected. Surely a method of treating the abscesses of Pott's disease which yielded in the hands of Bruns fifty successful cases out of fifty-two, and of Fraenkel, eighteen out of twenty, was one which deserved a fair trial before resorting to severer measures. If aspiration and the injection of iodoform emulsion proved unsuccessful, the method of evacuation recommended by Barker and Treves, with immediate closure of the wound, might be employed before resorting to open drainage.

Dr. Plimpton, in closing the discussion, said that the tube had been left in for free drainage, as it had been found that where it was removed shortly after operation, the exuberant granulations choked up the sinus, and gave rise to a great deal more trouble and discomfort than where the tube was retained. At the time of the operation, he had in mind the possibility of accident from having the tube in too close proximity to the femoral artery, and in this particular case there were dense cicatricial barriers between the tube and the artery. Small and not readily accessible abscesses should not be interfered with unless they cause some disturbance, but he would not hesitate, if circumstances seemed to demand it, to open them above Poupart's ligament. The existence of intra-abscess pressure and its effect upon the general health, was well demonstrated in one case in which he removed about half a pint of the contents of the abscess by aspiration, with the result of causing an immediate return of the child's appetite, and a prompt relief of his pain. He had seen the iodoform emulsion used in a number of instances without apparent benefit. In considering the percentage of abscesses which disappear spontaneously, it must be remembered that many of them are small abscesses, or are nothing but fluid in the joint, so that the statistics on this point were very defective.

Dr. L. W. Hubbard read a paper entitled "A Contribution to the Study of Non-deforming Club Foot."

Dr. Phelps objected to the name "non-deforming club foot," on the ground that all cases he had seen presented deformity.

Dr. Shaffer said that when he first called the attention of the profession to this subject, this name had suggested itself to him because all the conditions of club foot were present except the deformity, which was so slight that it had hitherto escaped observation.

Dr. V. P. Gibney said that the condition described some years ago under the name metatarsalgia might be confounded with non-deforming club foot. These patients usually complain of pain after sitting for some time, as in the theatre. He had treated a few cases of non-deforming club foot by division of the tendon and plantar fascia, over-correction, and retention in this position by plaster of Paris for a period of several weeks, and he had not been obliged to resort to extension subsequently. So far as he knew, these cases had not relapsed.

Dr. Shaffer said that in a series of twenty-two cases of metatarsalgia, he had relieved over one-half by the antero-posterior traction shoe alone. The inability to flex the ankle joint brought the maximum pressure at the point of irritation, and hence, by producing a certain amount of forcible flexion at the ankle joint, the pressure was brought upon other parts, thus removing the constant irritation which he thought was the chief etiological factor. He had permanently and completely relieved marked cases of non-deforming club foot within one week by three or four applications of his traction apparatus. In some cases, deformity can be reduced at one sitting, but the muscles re-contract slightly, necessitating a more prolonged treatment. He did not believe that tenotomy was necessary in any case of non-deforming club foot.

Dr. R. H. Sayre had found many cases of metatarsalgia to be dependent upon irritation of the pelvic nerves, and such cases had been relieved by galvanism with one pole over the sacrum, and the other over the ovarian region. In the treatment of non-deforming club foot, he sometimes employed stretching, and sometimes tenotomy, depending upon the nature of the case. If the tendo Achillis or plantar fascia gave a reflex spasm when stretched to its utmost, while joint pressure was applied, his experience had been that tenotomy was necessary. If no reflex spasm was produced, the contracted tissues could be stretched.

Dr. Ridlon asked if the author considered the woman exhibited by Dr. Whitman, to have a pure non-deforming club foot, and whether he would expect to fully relieve the disability and restore the full flexion by the use of a stretching apparatus.

Dr. Halsted Myers reported a case of non-deforming club foot in a man, 38 years of age, in which the etiology was unknown. The symptoms were unusual in that although the ankle flexion was only stopped at 95°, the principle complaint was that the knee could not be fully extended. The patient also felt that he could not fully extend his thigh without much more effort than on the other side, and also felt that his pelvis was tilted up posteriorly. The man knew nothing of anatomy, yet these symptoms were reasonable theoretically, for shortened gastrocnemii might cause knee flexion, and this, in turn, thigh flexion, and this again, tilting of the pelvis up posteriorly. The shortening of the gastrocnemii was the only deformity apparent, yet the subjective symptoms were so annoying that the patient himself proposed forcible extension and fixation in bed, for months even if necessary.

Dr. H. W. Berg said that he had seen many of the cases on which Dr. Shaffer's first paper was based, and not a little credit was due to him for having distinguished these cases from those of chronic rheumatism. Most of those described in the paper of the evening, had been so quickly relieved that he was inclined to think they were not congenital, for, after such a condition had lasted for many years, it did not seem reasonable that they should be relieved by one or two stretchings.

Dr. Hubbard, in closing the discussion, said that he had never seen a case of non-deforming club foot which he thought would consent to an operation for the relief of the difficulty, as the patients did not ordinarily consider it of much importance. Nor could he recall a single case which had not been materially relieved after one or two stretchings, except in those which were *rheumatic*.

In answer to Dr. Ridlon, he would say that he considered the case presented by Dr. Whitman, a typical one of non-deforming club foot of a rather pronounced type, but he had seen as bad, and even worse cases, relieved by persistent stretching. The treatment was prolonged in some instances by the re-contraction of the muscles, but just as india rubber yields after a certain number of stretchings, so these cases will be permanently relieved after the continued use of the traction shoe. In the case referred to in the paper, the condition had lasted for a long time, and the muscle was well developed, and the time of treatment was still further prolonged by the patient's intolerance of the stretching.

A NEW APPARATUS FOR OVERCOMING THE ABDUCTION OF THE THIGH IN HIP JOINT DISEASE.

Dr. Newton M. Shaffer exhibited a new apparatus which he had devised for the purpose of overcoming the abduction of the thigh in hip joint disease, and at the same time avoiding the infliction of any traumatism upon the joint. It consisted of a thoracic attachment to the ordinary long hip splint, with an arrangement of curved levers actuated by a key, by which motion is imparted to the limb in a direction downwards and inwards, instead of as in other instruments of this class, inwards and upwards. This is the chief feature, and it is on this account, that traumatism is avoided. It can be attached to any ordinary long traction splint, and like the thoracic part, it is to be used only as a temporary arrangement for reducing the deformity.

Dr. Phelps said that he was glad to see that Dr. Shaffer had come to recognize the fact that we cannot act upon the hip joint with any degree of precision without taking hold of the thorax; but he failed to see any necessity for such an apparatus in our armamentarium, as his lateral traction splint did the same thing, and no case of hip joint disease need recover with angular deformity. Since he had devised and made use of his lateral traction fixation splint, which acts on the same principle as the apparatus just exhibited, he had not seen a case in his practice of angular deformity. If such a thoracic splint be applied after the deformity has once been overcome, recovery must take place without angular deformity.

Dr. Shaffer explained that the apparatus he had just presented, was intended only as a temporary apparatus for overcoming persistent abduction of the thigh, and he considered it a very serious mistake to use the thoracic attachment in the ordinary treatment of hip joint disease, because it limited the motion of the spinal column, and this would necessarily increase the strain upon the diseased joint. It was for this reason, that he had discarded the thoracic addition to the hip splint many years ago. The idea of his new apparatus is to provide a temporary means of overcoming abduction, and it is only to be worn long enough to accomplish this purpose, and then it is so arranged that the abduction and thoracic portions can be readily removed, leaving the ordinary hip splint, which permitted a free movement the dorso-lumbar spine, and thus diminished the traumatis at the hip, which is best shown when a patient with hip joi disease and dorso-lumbar caries, attempts locomotion.

NECROLOGY.

A. M. Pollock, M. D., of Pittsburg, Pa.

Death has touched him with his dart, the honorable an skilful physician and surgeon, Dr. A. M. Pollock. He die June 20, 1892, after a long illness, full of years and experienc I first became acquainted with this honorable gentleman i 1866, since when he has assisted me in many difficult an complicated cases at all hours of the twenty-four. I alway felt that I had no ordinary prop to lean upon in trying an difficult cases. He did not practice his profession for glor but for the benefit of his patients. He was unassuming modest, quiet, cheerful and gentlemanly in the sick room and rather than claim the credit himself for what assistanc he might give or what light he might throw on a case, he woul give the attending physician full share of the honor tha might be derived from his counsel. He never be-littled th attending physician to his patient, or to his friends. He alway left the attending physician after a consultation with mor of the patient's and patient's friends' confidence than befor the consultation. He would not suggest a change in treat ment unless it was actually necessary for the benefit of th patient, and then it would be made in such a gradual man ner that it would be passed unnoticed. He had the "touc of a lady" and whilst he may not have had the other tw attributes of the surgeon "the heart of a lion and the eye o an eagle." yet he had other qualities which are far higher—good judgment, skill, caution and conscientiousness. He would not operate for the sake of operating. He would feel morally certain that the operation would benefit the patient before he would consent to perform the operation, and now that he has gone his loss will be deeply felt. His chair is vacant. We shall miss him socially and professionally. May God bless him. His works will follow him. J. M. B.

Dr. Henry F. Formad, of Philadelphia, who died recently, was an eminent physiologist and original investigator. He was born in Russia about forty-five years ago. While yet a lad, he was called upon to serve in the medical department of the Imperial army. He was suspected of political heresies, and he became an exile after having served a term of imprisonment. He went to Berlin and Heidelberg studying medicine and microscopy, especially; at the latter place he took his degree, with honors. He became for a time a *docent* in histology and microscopy, which subjects were then comparatively little developed or taught. With Dr. Wier Mitchell he made some original researches as to the poisons emitted by insects. With Dr. H. C. Wood, he did some work for the authorities at Washington, regarding the infective processes of diphtheria. The results were published about 1880. He became a member of the American Medical Association in 1889.

Dr. William Randall Birdsall, of New York, died on the 7th of June, aged forty years. He was a graduate of the University of Michigan and College of Physicians and Surgeons, New York, about sixteen years ago. His specialty was that of the nervous system and he held the physiciancy in the department of nervous diseases in the Manhattan Eye and Ear Hospital. He was a member of the Academy of Medicine and numerous other Societies.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JULY 2, 1892.

BY-LAW IV OF THE AMERICAN MEDICAL ASSOCIATION.

The Publication of Papers and Reports.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

NEW CASES OF INDIGENOUS FILARIAL DISEASE.

In a recent number of *Public Health*, MR. AUSTIN WILLIAMS, of Liverpool, reports a case of filaria sanguinis hominis, occurring in that city. About one year ago, an adult male noticed that his early morning urination was followed by a few drops of blood mingled with, or suspended in a jelly-like mass. After a few negative examinations with the microscope had been made, the suspected filaria was discovered. This chyluria has continued until the time of report. Hæmaturia of a severe character has also occurred, the blood appearing most copiously in the morning. This attack subsided after a time, and then the patient's condition relapsed to his usual state of passing a drop or two of blood, with chylous urine, on rising in the morning. The man has never been out of England, nor very far away from Liverpool. MR. WILLIAMS knows of no other possible way in which his patient could have contracted the disease, except that he has been exposed to the emanations from the intestines of animals, some of them imported from southerly ports, which animals may have been infested with this parasite. A physician of DR. WILLIAMS' acquaintance, name not given, has informed him privately of a case of chyluria in the person of a man, whose duties brought him into contact with imported cattle.

In August of last year, DR. R. M. SLAUGHTER, of Theological Seminary, Virginia, found two apparently indigenous cases in his State. He has given a report of his cases, with an illustration, in the *Medical News* for December 5, 1891. While engaged in microscopic work, he was surprised to find in the urine of two patients unmistakeable evidence of the embryo form of filaria sanguinis. Indigenous cases have been reported from Charleston, S. C., to the number of twenty-two, by DR. DE SAUSSURE; also one other case by DR. MASTIN, of Mobile. Adding the two cases of DR. SLAUGHTER to those, there have been reported just twenty-five cases in the United States, believed to be indigenous.

DR. SLAUGHTER made a careful investigation at the Library of the Surgeon-General of the Army at Washington, but he was not able to increase the total beyond the twenty-five cases just referred to: it is true that other cases of filaria sanguinis have been reported, but they were not of indigenous origin. Those cases had been imported from tropical countries.

The cases reported by MR. WILLIAMS and DR. SLAUGHTER have enlarged the bounds of this variety of indigenous parasitism to and beyond the thirty-eighth parallel of latitude, north. They are probably the first recorded cases of their kind in their respective localities. The condition of the blood was reported as to none of these three cases. DR. SLAUGHTER had desired to examine the blood of his two cases, but had not been able to do so. Embryo filaria was found in the pus of an alveolar abscess in one of his cases that showed a tendency to the production of furuncles. The hæmato-chyluria of these cases appears to have been the maximum of pathological results; the lymphatic manifestations so frequently observed in chronic filarious infection, such as chylocele, lymph-scrotum, lymph-leg, lymphangitis, glandular tumors and abscesses, etc., etc., were absent.

All cases of chylous disease should be investigated microscopically. Many of them have been so examined in recent years with negative results. One such we recall as having occurred not long ago at the Philadelphia Polyclinic, in the practice of that admirable clinician, DR. SOLOMON SOLIS-COHEN. The patient was a colored lad, from the island of St. Thomas, having chyluria. Although repeated examinations of both urine and blood were made by the reporter and by the late Dr. Joseph Leidy and by Professors Tyson, Heilprin and Griffith, the suspected parasite was *not to be found*. In the case of the Charleston chylous series many negative examinations were made prior to 1886. Finally in that year, Dr. John Guiteras was the first to detect the embryo specimen in chylous urine and in blood. The embryo worm is somewhat elusive of microscopic research. The following description taken from Dr. Rudolph Matas' contribution in the *New Orleans Medical Journal*, January, 1891, shows why the helminth is most successfully sought in fresh fluids: "When first seen under the microscope the parasite presents itself as a transparent and almost structureless little worm, which moves with vigorous and graceful serpentine movements in the blood current, dashing along and ploughing its way rapidly through the mass of blood corpuscles. If the medium becomes dry, these organisms *become granular and assume a striated* appearance owing to the retraction of the enveloping membrane, or chorionic sac. If they are abandoned in an extravasated fluid, or in urine, or in ascitic liquid, they become invisible after a certain time."

The therapeutics of filarial disease are commonly aimed at the removal of the adult worm by some appropriate surgical procedure. No specific remedy antagonistic to the embryonic form that roams through the circulation has yet been found. Thymol, however, has been reported upon favorably from India by Surgeon-Major Lawrie. He has given to the *Lancet* reports of two cases of apparent cure of chyluria of filarious origin by one grain doses, every four hours, gradually increased to five grains. Dr. Solis-Cohen, in the case already referred to, made use of a placeboic remedy which to the mind of his patient exhibited the "startling virtue" of clearing up the milky urine, and by the end of a week making it "perfectly clear." Now this remedy chanced to belong to the aromatic vegetable group as well as thymol; it was aqua menthæ piperitæ, given in six drop doses thrice daily. Can it be possible that there was enough of remedial potency in that mint-water, superadded to the effects of this more northerly climate upon a lad —who had been nine years absent from the hot-bed of filarial infection—to stamp out the last particle of vitality in a moribund and expatriated parasite, and really clear away a last feeble barrier to the normal flow of the chylous circulation? Let the answer be what it may, there can be no harm in suggesting that some of the products of thyme and mint may be serviceable in chyluria and other chylous cases, whether their origin be shown to be filarial or not; the treatment to begin after having made a check-examination with the microscope of both blood and urine of the patient. It may be that the vegetable aromatics are the *appropriate antagonists against* certain forms of animal parasitic infection.

THE THIRD ANNUAL SESSION OF THE ASSOCIATION OF AMERICAN MEDICAL COLLEGES.

One of the most important of the National Associations holding their annual meeting contemporary with that of the meeting of the American Medical Association is the above named body. Its third annual session, recently held at Detroit, was most successful. Among the list of new members we observe Harvard represented by Prof. Harrington, and Woman's Medical College of Pennsylvania by Prof. John B. Roberts. The membership now includes two-thirds of the regular schools of the United States, including nearly every well established reputable institution. The exception to membership is *notably from the schools of the Southern States*. The situation in the South is best explained in the statement of a representative of one of these schools in a communication withdrawing from membership in this body. He says unless certain other competing colleges *in my locality join*, we cannot remain a member, and consequently withdraw until such time as these colleges see fit to join us in promoting this desirable reform. We are of the opinion that the intelligence and pride of the South is such that the representatives of these colleges will not require repeated urging, but that they will indicate by their immediate action that they purpose keeping abreast of the recent reforms in medical education. We believe the near future will see this a very strong society, including in its membership all the reputable colleges of the country. There is no urgent reason why the representatives of colleges themselves should not meet together as occasion requires, and in a business-like manner correct their own abuses, as they may exist, and receive that benefit certain to come from mutual gathering of bodies of people pursuing like avocations, and whose thoughts pursue the same channels. Representative bodies of this character have become a social and business necessity. We have our National associations representing our different business, church and educational interests. The bodies representing the professions of dentistry, pharmacy, engineering, etc. If we mistake not, a successful *organization* of this character will render less necessary such urgent appeals for the regulation of medical practice and medical education by State legislation. The action of the American Medical Association in endorsing the "minimum of requirements" of the college association, and directing the Secretary, Dr. Atkinson, to so notify the different colleges, is suggestive of professional sentiment at the present time. The papers of Drs. N. S. Davis and Victor C. Vaughan were well worthy of their distinguished authors. The title of the first paper was "To What Extent Should Clinical Instruction be Afforded Students of Medicine in Regular Courses?" and of the latter, "To What Extent Should Laboratory Instruction be Afforded Students of Medicine in Regular Course?" The discussion upon the paper of DR. VAUGHAN was postponed for one year, and DR. RIGNELL H. FITZ, of Harvard, invited to open the discussion at that time. DR. VAUGHAN's paper outlined a very comprehensive course, well adapted to the new course to be enforced at the university he represents. Its practical enforcement by the colleges would render easy the solution of the question of higher medical education in the United States. DRS. N. S. DAVIS and PERRY H. MILLARD were reëlected President and Secretary.

As the mouthpiece of the great body of medical men in this country, THE JOURNAL welcomes the new organization, and bespeaks for them a bright and most useful future.

MISTLETOE AS AN OXYTOCIC.

In the *Medical News*, DR. H. P. HOWARD, of Virginia, reports his personal experience with mistletoe as a substitute for ergot. In one case of very protracted labor, where there was apparent cessation of uterine contraction, the drug was of signal benefit, after a variety of other measures had been resorted to without the least benefit. He used the fluid extract at irregular intervals, with the effect of terminating labor in about five hours. There were produced a typically normal uterine contraction, both as to strength and regularity. The third stage of the labor was ended by the same pain as that which followed the expulsion of the fœtus. The womb then contracted firmly, promptly, equably and with a minimum amount of hæmorrhage. In this case delivery was almost wholly uterine in action. The patient was a chronic sufferer from cardiac asthma from mitral lesions and hypertrophy, also peritoneal inflammatory complications; so that any sustained abdominal efforts were out of the question, or if they had been relied upon, the labor must have terminated in death. In this view of the case, the author accords to the drug the largest share of credit for the unexpectedly favorable outcome of the parturition. The author gives some literary information regarding the history of mistletoe as an oxytocic. DR. W. H. LONG, of the United States Marine Hospital Service, published in 1878, some favorable results from a ten years' trial of the drug. He claimed that he had found it superior to ergot in labor. He advocated the use of the drug in post-partum hæmorrhage, menorrhagia and hæmoptysis. DR. LONG's paper appeared in *New Preparations*, and in the *Louisville Medical News*, for the same year, 1878. In DR. LONG's opinion the drug was capable of producing intermittent uterine action, as distinguished from the tonic contractions caused by some other oxytocic medicines.

About forty years ago, DR E. B. TURNIPSEED called attention to the fact that mistletoe had a certain popular reputation as an aborti-facient. His paper was published in the *Charleston Medical Review*, in one of its earlier volumes. The general therapeutical rating of mistletoe is that it is inert, unmanageable and obsolete, whereas neither of these designations may be the truth.

ARTIFICIAL URETHRA IN PROSTATIC OBSTRUCTION.

An article in *Medical Press and Circular*, May 11, gives to DR. HUNTER MCGUIRE, the newly elected President of the American Medical Association, the credit of priority, over one or two French surgeons, in planning and performing his operation for the relief of chronic prostatic disease. The writer states the dates and places of publication of first papers on the subject sufficiently to prove DR. MCGUIRE's precedence. He says that he notices the matter because he thinks "that it is very desirable that the praise and credit of devising and successfully completing a new and much required operation should be *justly* awarded; and we feel that our contemporary *L'Union Médicale* and our professional brethren in France would not unwittingly deprive one of the most distinguished surgeons of the English-speaking peoples, DR. HUNTER MCGUIRE, of his well-won honor."

It was at the convention in 1888 of the American Surgical Association, that the first two cases of DR. MCGUIRE were reported. His paper was published in volume six of the Transactions of that Society, under the caption of "The Formation of an Artificial Urethra in Prostatic Obstruction," and a later contribution, entitled "A Report of Twenty-one Cases of Supra-pubic Cystotomy, with Remarks," appeared in the eighth volume of the same Transactions.

Two French surgeons have done the same or a similar operation for cystitis and prostatic hypertrophy. The former of these was probably DR. F. VERCHERE, who in the early part of 1889 made a supra-pubic fistula under the guise of an artificial urethra. Following him DR. PONCET has operated not less than thirty-five times upon cases of enlarged prostate that were not remediable by less serious surgical intervention. The writer in *L'Union Médicale* describes the PONCET procedure as "an anterior supra-pubic, artificial urethra which will be of very great service in chronic prostatic disease." The advantages of the operation were not admitted by all the surgeons who discussed DR. MCGUIRE's paper in 1888, although PROFESSOR GROSS congratulated the author that he had been enabled to bring out the new operation based upon the physiology of urination and mechanism of the bladder. Among the other surgeons who offered their views on the subject at that time were Sir William MacCormac, Reginald Harrison, Annandale, Arthur Durham, Hingston of Montreal and Hayes Agnew. The greater number of these were wedded to the older methods, while some of them regarded the supra-pubic operation as dangerous out of all proportion to the benefits to be obtained. Dr. Agnew took the position that a skilled operator may do the supra-pubic section with perfect safety, while an inexperienced person might unexpectedly find himself doing an intra-peritoneal operation. Dr. McGuire remarked that in his operations he had not met with the peritoneum.

EDITORIAL NOTES.

Prevention of Blindness.—A committee was appointed by the Medical and Chirurgical Faculty of Maryland in April, 1891, to devise means for lessening the amount of blindness from curable diseases. This committee prepared a circular which was sent to the midwifes of Baltimore explaining the dangers of ophthalmia neonatorum, and giving directions for cleaning the eyes of the newly born. The necessity for prompt medical interference at the first sign of the disease was also insisted upon.

In addition, in the waiting rooms of the various dispensaries of the city they placed placards, reading as follows: "Watch a baby's eyes carefully for a week after birth. If they look red, or run matter, take it at once to a doctor. The child may become blind if not treated properly." Such work can hardly fail to prove of much value, and should be imitated elsewhere.

A Fee Arbitrated and Promptly Paid.—The readers of The Journal will be glad to learn that Dr. F. E. Waxham has received two thousand dollars for his services in a case of intubation for diphtheritic laryngitis. The parties disputed the bill for six months and at last put it in arbitration. The full charge was allowed, and promptly paid by the happy father.

The College of Physicians of Philadelphia.—The College has been fortunate in receiving lately gifts of two portraits. Dr. H. C. Wood, for the profession of Philadelphia, gave a fine picture of Dr. Alfred Stillé. Dr. Mitchell, President, presented another portrait, that of Dr. Oliver Wendell Holmes, which was accepted by Dr. J. M. Da Costa, Vice-President. Dr. Holmes was prevented from being present, but he sent a reply in verse which contained numerous references to the convention of 1847 of the American Medical Association, held in Philadelphia, which was at that period the medical Athens of America. The poem of Dr. Holmes was read by Dr. Mitchell, who explained some of the more recondite allusions of the poem. Dr. Mitchell also contributed a poem of his own to accompany his admirable gift. The portrait of Dr. Holmes is the work of Mrs. Sarah Whitman, and is thought by many to be the most satisfactory counterpart of the poet-doctor ever made; he is represented life-size, half-length, and is garbed in the black robe of the Philadelphia College.

The papers have announced that the College will receive a bequest of $1,000 under the will of Dr. D. Hayes Agnew.

Medical Bequests of the Late Dr. Agnew.—Dr. Agnew has left an estate appraised at a quarter million. To the University of Pennsylvania he has given all his right and title in his great surgical text-book, also numerous specimens and drawings appropriate to pathological teaching. After the death of his widow the University Hospital will fall heir to $50,000. The Maternity and Kensington Hospitals will then receive $1,000 each. An equal amount will go to the College of Physicians.

Surgical Terminology.—At the Surgical Congress held at Paris, in April last, Dr. Ferrier treated of hepatic surgery, and gave specimens of the enriched vocabulary of that rapidly growing department. Among the terms mentioned were hepaticostomy, hepatostomy, cholecystostomy, choledocholithotripsy, cholecystenterostomy, cholecystolithotripsy and some others; nearly all of them derived from the Greek language and expressing some newly proposed operative modification.

ABSTRACTS.

Methylene-Blue in Malarial Fever.—W. S. Thayer (*Bull. of Johns Hopkins Hosp.*, May, 1892). In consideration of the fact that methylene-blue has the power of staining the malarial plasmodia in the cells of fresh blood as well as in dried blood, Guttmann and Ehrlich originally suggested its use in malarial fever. They observed two cases. The first was one of tertian ague to whom one dose of 0.5 G. (7½ grs.) of methylene-blue was given No malarial organisms were found in the blood after the third day. The second case was one of quotidian ague and under the use of the remedy, the plasmodia disappeared from the blood after six days. Thayer has observed seven cases of malaria treated with methylene-blue in Prof. Osler's wards.

In the first case, one of tertian ague, the patient was given 0.1 G. methylene-blue in capsules five times a day. On the next day the temperature rose to 105° but there was no chill. After this there were no further malarial symptoms, but the organisms did not disappear from the blood until the third day. The remedy produced burning with micturition and vesical tenesmus. The second case was one of chronic remittent fever with hyaline bodies and pigmented crescents in the blood. The temperature fell to nearly normal in five days, and there was marked diminution in the number of organisms. During the next month irregular, slight febrile attacks occurred, and with eventually an increase in the number of organisms in the blood. It seems from the report that the patient received the methylene-blue regularly for about four weeks, also toward the last of this period, Fowler's solution. Finally quinine was given in four grain doses three times a day, with return of the temperature to normal. The quinine was continued for eleven days and at the time of his discharge, the blood showed an occasional hyaline body, and pigmented crescent. His general condition improved rapidly under the quinine. The remaining cases illustrate more fully the features of the first two. The cases were all carefully observed, and the following conclusions which Dr. Thayer offers, seem fully justified by his report:

1. Methylene-blue has a definite action against malarial fever, accomplishing its end by destroying the specific

organism; but it is materially less efficacious than quinine, failing to accomplish its purpose in many cases where quinine acts satisfactorily.

2. The action appears to be rapid, the chills disappearing [illegible] the temperature, in the remittent cases, falling to normal during the first four or five days; but later, however, if a sufficient number of organisms have resisted the drug, they appear to develop again directly under its influence, causing a return of the symptoms.

3. Methylene-blue seems to have no advantages over quinine which would warrant its further use.

Giant Growth of the Colon.—H. F. Formad (*Univ. Med. Mag.*, June, 1892). Dr. Formad recently exhibited a very unique specimen before the College of Physicians, Phila. The specimen was an enormously developed colon. The patient from whom the specimen was taken was a man 29 years of age who had been found dead in a water closet, and thus became the subject of coronial investigation.

His history as obtained from his mother, shows that up to the age of eighteen months he was a normal infant with the exception of a rather large abdomen, some irregularity of the bowels and attacks of constipation. The abdomen continuously increased in size, and the constipation became more marked. At sixteen he would go as long as a month at a time without a movement of the bowels. At twenty years of age he was exhibited in a dime museum as the "Wind bag" or "Balloon Man." Lately he had abdominal pain, tympanites, and shortness of breath. At the autopsy the colon was found to be 8 feet, 4 inches long, and its circumferential measurement at various parts as follows: Cæcum 10 inches; ascending colon, 15 inches; transverse colon gradually increasing from 15 to 30 inches; descending colon, 25 inches; sigmoid flexure 25 to 27 inches. The rectum was of normal size. The meso-colon was abnormally large and thick. The colon contained about two and a half pailfuls of fecas, which weighed forty pounds. The coats of the colon appeared to be normal. The other viscera were normal but displaced to accomodate the colon. There was no evidence of an obstruction and Dr. Formad regards the case, not as one of ordinary dilation from retention of feces, but an actual overgrowth of colon.

Phenacetine in Urinary Troubles.—Traill Green (*Univ. Med. Mag*, June, 1892). The writer calls attention to the relief which phenacetine has given in his hands, in cases of frequent micturition in old people. He calls attention to the well known fact, that old people are often troubled with strongly acid urine, which calls for frequent micturition. At times this so interferes with rest at night as to seriously interfere with their general health. He has recently been in the habit of prescribing in such cases, 10 grs. of phenacetine at bedtime, with generally complete relief of the symptoms. He does not recommend its use in enlargement of the prostate.

Piperazine in Gout.—Schmidt (*Jour. de Méd. de Paris*, May 22, 1892). Schmidt advises the employment of this remedy, which holds an important place in the treatment of gout, in the following ways:

1. In a dose of 1 G. (15½ grs.) daily dissolved in simple water, or in Seltzer water.

2. In .5 per cent solution, piperazine causes no irritation of mucous membranes, so that a solution of this strength is suitable for lavage of the bladder, and gradual dissolution of uric acid calculi there.

3. Owing to its ready solubility in water, it may be used in 10% solution for direct injection into the uric acid tophi themselves.

4. Piperazine, ½ gram; Alcohol, 20 gram; Water, 80 gram. This solution may be used on compresses as a direct local application to gouty deposits, and will favorably influence the action of piperazine administered by the mouth.

DOMESTIC CORRESPONDENCE.

To the Editor of the Journal of the American Medical Association:

In giving the following statement, as the result of a careful investigation of the sanitary condition of the Hotels Ponce de Leon, Alcazar, and Cordova in St. Augustine, Fla., and of such accounts of the cases of fever which occurred in guests of these hotels during the spring of 1892 as it has thus far been possible to obtain, I am satisfied that no one of these cases of fever was caused by the water supply, or by the drainage of the buildings, or by anything connected with them or their surroundings. The water supply has been examined chemically and bacteriologically, the plumbing and house drainage of each hotel have been carefully scrutinized, the sources of milk supply, of ice, and of fresh vegetables for the use of the guests of these hotels have been investigated, and no causes of disease have been found in any of them. There have been no cases of typhoid fever among the residents in St. Augustine during the past year, and the general sanitary condition of the town is excellent.

Between December 15, 1891, and April 25, 1892, about 25 cases of typhoid fever are reported as having occurred in about 25,000 persons who visited St. Augustine. Fourteen of these cases occurred among visitors while they were in the town—and eleven are said to have occurred from two to three weeks after the patients had left the town. In addition to the above, four cases are reported in hotel servants and one in a nurse. Seven of the cases in visitors while in the town were in the Hotels Ponce de Leon, Alcazar, and Cordova, and six of the cases reported in persons who had been gone from two to three weeks were also in guests of these three hotels. In all, therefore, out of about 1,600 guests of these hotels, thirteen are reported as having been affected with typhoid. The investigation into the details of these cases is not yet completed, and I can only say now, that it is probable that two or three of them were not typhoid fever at all, that two of them were ill on the day of their arrival, which illness became well marked typhoid five days later, and therefore, was not contracted at St. Augustine, and that of all the cases at the above mentioned hotels, there were among the guests but three which it would seem must have been contracted during their stay in St. Augustine. The four servants affected with typhoid probably had the specific cause introduced into their bodies through contact with a fever case, or cases, or with soiled linen from such case.

Every educated physician will understand from the above figures, the extreme improbability that so few cases, scattered over a period of two months, and giving a ratio of less than one to a thousand people exposed, could have been due to anything in the structure of the buildings, the general water supply, or the food, milk or ice—and the detailed investigation of all these things makes it practically certain that no case of typhoid was due to any of them.

Whether the investigation, now in progress, into the history of the reported cases will indicate the source of the disease, is of course, doubtful, and probably the cases had no common source, but were each contracted at a different time and in a different place—but knowing, as I do, the great interest in these Southern winter health resorts felt by a large number of Northern invalids, it has seemed best to make this preliminary statement in order to assure them that they can make their plans for going to St. Augustine next winter with perfect confidence that—while absolute security can be had nowhere—so long as they are there they will probably be less liable to be exposed to the contagion of typhoid fever than they will be if they remain at home.

I. S. BILLINGS, M.D., Surgeon U. S. A.

BOARD OF HEALTH OF ST. JOHNS COUNTY.

ST. AUGUSTINE, FLA., June 10, 1892.

We, the Board of Health, of St. Johns County, Florida, do hereby certify that, prior to the month of April A. D. 1892, there were no deaths reported to this Board resulting from fever of any kind, nor does this Board have any knowledge of the existence of any case of fever in the City of St. Augustine, or St. Johns County prior to the period above mentioned; that during the month of April A. D. 1892, the following deaths from fever were reported to this Board.

1. Florence Hawley Glover Clark, white, female, age 37 years, residence Newton, Conn., died April 3, 1892, cause of death typho-malarial fever, reported by F. Fremont Smith, M.D., attending physician.
2. Elizabeth M. Park, white, female, age 35 years, residence Rye, New York, died April 5, 1892, cause of death typho-malarial fever reported by F. Fremont Smith, M.D., attending physician.
3. Joseph N. Knight, white, male, age 34 years, residence Highwood, New Jersey, died April 14, 1892, cause of death, typhoid fever, reported by F. Fremont Smith, M.D., attending physician.
4. Irene L. Davis, white, female, age 26 years, residence Philadelphia, Penn., died April 17, 1892, cause of death, typhoid fever, reported by F. Fremont Smith, M.D., attending physician.

That all of said deaths occurred in the City of St. Augustine; and that since the 17th day of April, 1892, there has been no report to this Board of death from fever of any kind.

We further certify that the rules of this Board require attending physicians to report deaths to this Board within 24 hours after the same occur; and that all deaths are so reported by the physicians of this county in whose practice a death may occur; that at the present time we have no knowledge of the existence of any case of fever in the City of St. Augustine, or the County of St. Johns, but the certificate of practicing physicians in this city and county, is, in our opinion, the best evidence as to whether or not fever of any kind exists here at the present time.

We further certify that the sanitary condition and healthfulness of this city and county are very good and have never been better.

[SEAL.] WM. F. SHINE, M.D.,
Pres't St. Johns County Board of Health.
(Signed) T. E. B. KERNAN, A. J. CORBETT, SEC'Y.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

In THE JOURNAL of June 25, is published a report of the proceedings of the meeting of June 8. In that report there is nothing said of my substitute or amendment to Dr. Willis P. King's motion in regard to the committee of five from the American Medical Association, and one of five from the New York State Medical Society. My amendment added five from the New York State Medical Association. It was carried. The report reads: After further discussion Dr. Gihon offered the following amendment to Dr. King's resolution, which was accepted by the latter. Then follows the resolution, in which the names of Drs. Potter and Vander Veer are mentioned. Their names were not mentioned in the original motion. It was so decided next day.

Sincerely Yours, J. G. TRUAX.

New York, June 27, 1892.

FOREIGN CORRESPONDENCE.

Public Vaccination in Berlin.

There are to be seen in Berlin at the present time multitudes of children bearing their school-books under one arm, while the other (always the left), has pinned conspicuously to the sleeve of the outer garment the Geneva Red-cross. On inquiry of one of the urchins, he immediately divested his arm of its covering and exposed to view six typical pustules of vaccination, and explained for my further edification that the Red-cross meant *nicht Drucken*—not to press rather a quaint idea.

Pursuing the subject farther, I have been able to obtain such information which I am led to believe places vaccination as to its methods, etc., on a plane rather different from that as at present practiced in America. On invitation of a colleague to whom I expressed the wish, I was enabled to see him vaccinate upwards of 200 children in a session lasting scarcely an hour; of the method employed I shall speak hereafter.

The gathering at a specified time of some fifty mothers with their babes, besides 150 other children whose average age is 12, for vaccination, is the finesse of a system which probably only such a Government as this can carry out. The authorities knowing of all births, a postal card is sent to the parent of a child born the previous year to bring the infant on such a day for vaccination, under penalty of a fine; besides, the law reads, all children approximating the age of 12 must be revaccinated under the same penalty. This is a *compulsion,* and it is this that makes the system here such a perfect one. The peculiarity of the law makes a child born December 31, 1891, undergo vaccination in 1892, while if its birth occurred a day later it would not be vaccinated till 1893, provided in all cases it be fit; *i. e.*, not suffering from disease, when if that be the case, a record is made of the fact, and the child is not bothered till the following year.

Thus in its first year the child is vaccinated, and again at 12; then, as far as the female portion of the population is concerned, the matter ends. As regards the male, he is revaccinated when he joins the military, and then only for sanitary precautions taken in all such large bodies. While this latter point may have some weight, still the theory of susceptibility differs much from ours, exemption being considered fully attained when the subject has been, as above described, vaccinated twice. It need scarcely be mentioned that where small-pox appears in a family the entire house is vaccinated. The entire house in Berlin, by the way, consists of from fifteen to thirty families, and therefore quarantining is impossible.

As regards compulsion with us at home, while it is thoroughly practiced in the schools, there are still quite a number of children who are not included, and who have escaped the vigilance of the district vaccination physician. We have compulsion at quarantine which has reached perfection, but there are some children born in America who up to a late date could pass peaceably enough through life without the well-known scars. Probably Cook County, Illinois, owing to its Compulsory Education Law, for which we ought to be thankful, is one of a very few places where vaccination is complete and thorough. To illustrate which I mention a case of *primary vaccination* in a child of 10 who, born by the aid of a midwife (whose highest ambition was probably to collect her fee), grew in poverty and ignorance till he attained that age when he could help earn something for the maintenance of the family. The Compulsory Educational Act coming into effect, the boy was surprised, pleasantly we may hope, by having his face washed, some neat apparel given him and sent to school; afterwards to the physician to fill out the vaccination certificate. In this case nothing was discovered on either arm but the accumulation of dirt of years, which on removal could not unearth a single scar. Fortunately, these cases are now exceedingly rare, and it is questionable whether in a little while they will not disappear entirely.

As to the methods. I saw the vaccination physician operate on some 200 cases in a series of 2,000, and his *modus operandi* is worthy a description.

The animal lymph which is supplied by the Government in liquid form, and is sent in minute glass tubes containing a sufficient quantity for fifty or one hundred vaccinations, each tube bearing the number of the calf from which the lymph is taken; a report being made by the physician as to its qualities by its effects on the patients. To be noted in this connection is the fact that if the vaccination does not take the first year, it is compulsory on the part of the parent to bring the infant a second year, and if no result is then attained again the third year, which proves final whether the vaccination is successful or otherwise.

The vaccination knife of Kerstein was used. It consists of a blade which is as thin as a spatula, sharpened on both edges, and whose length is 1 inch with a width of ¼ inch, which does not taper to a point, but is ⅛ inch wide at its tip; it is with this tip that all the incisions are made. The skin of the arm is made tense and, in case of a babe, four incisions are made on each arm after the tip has been slightly dipped into the lymph, once for each arm. With the infants antisepsis is practiced, wetting the blade in water after each vaccination and cleaning with antiseptic cotton. In the grown children antiseptic precautions are not used, and six incisions are made, but only on one arm. Of paramount importance in all the cases is the art of incising without drawing blood, in that event the lymph is liable to be washed away, and I must confess that I failed to see a single drop of blood from any of the incisions, which numbered over a thousand.

I was afforded an opportunity of noting the result of this method of vaccination by observing the same 200 subjects that I had seen vaccinated, who came eight days later to report and to receive their certificate. They all showed the typical pustules, and scarce in any case, of the infants especially, was there any failure of a single incision to produce its characteristic sore. As regards this the law is that in case of infants, if but one pustule results, it must be immediately revaccinated, the physician using the contents of the pustule for that purpose; while in the grown children, if but one incision "takes," that is sufficient.

One can conclude from this that the vast majority of physicians here, as it is now with us, pass their lives without seeing a single case of small-pox, and know only of the disease by its description in the books.

Jacob Rosenthal, M.D.

Berlin, June 7, 1892.

SELECTIONS.

A Worthy Sanitary Feat Quietly Accomplished.—It is alleged for General Rusk that he has greatly improved the treatment of cattle exported to Europe for food purposes. The mortality among them at sea, resulting from cruelty, want of water, etc., was formerly stated at 16 per cent., while at the present time it is 1 per cent. The value of these exportations is not far from $25,000,000 annually. If this statement is only partly true, General Rusk has accomplished a great sanitary reform, for he has been the means of indirectly purifying the flesh-food supply of thousands of European consumers.—*New York Med. Journal.*

Effects of an Overdose of Codeine.—An overdose of codeine is not a common occurrence, and therefore Dr. Mettenheimer, who has met with such a case, has reported it. An elderly lady consulted him for a slight catarrhal nonfebrile affection which, however, gave rise to a troublesome, spasmodic form of cough. For this he prescribed 0.03 gram (about half a grain) of phosphate of codeine, in the form of a pill, to be taken every three hours. The patient, however, swallowed four of these pills, or about a grain and a half of the codeine salt, at once. Shortly afterwards she vomited twice and suffered from abdominal pain. There was, too, suppression of urine and she felt very ill, being sleepy but unable to go to sleep. The next day she was still drowsy and had no appetite but there was no return of the sickness. She was then seen by Dr. Mettenheimer, who found the pupils hard and contracted, the pulse hard and quick, and the respiration accelerated. The cough had entirely disappeared. The contracted state of the pupils, the loss of appetite, and the abdominal pain persisted for several days. No urine was passed until thirty-six hours after the pills were taken. On the third day the drowsiness had passed away. The cough did not return for a week and when it did it was comparatively slight. This case seems to show that codeine in large doses has a very similar effect to opium and that it may prove a most efficient remedy for some kinds of cough. As the tongue remained clean it would appear that the vomiting was due to cerebral, rather than to gastric, irritation. —*The Lancet.*

The Pancreas and Diabetes.—Professor Seegen, one of the chief authorities upon diabetes in its physiological as well as its clinical aspects, recently read a paper before the Medical Society of Vienna, in reference more particularly to the recent researches upon extirpation of the pancreas and diabetes, and having regard to Lépine's explanation that the pancreas produces a glycolytic ferment, the lack of which causes an accumulation of sugar in the blood. Professor Seegen says that, granting that the blood of a diabetic patient has less glycolytic action than that of a healthy subject, it is assuming a great deal to hold that this proves the presence in health of a special glycolytic ferment manufactured by the pancreas. By careful experiments he finds that the normal sugar disappears most rapidly from freshly drawn blood when the latter is maintained at a high temperature (39° C.), whilst a current of air is being passed through it. That this is not due to the action of living protoplasm he shows by the addition of chloroform (to kill the protoplasm), which makes hardly any difference in the glycolytic action. Moreover, since the glycolysis goes on more actively after the blood has been drawn for some time than at first, Professor Seegen infers that the ferment is produced by some change in the blood outside the body rather than by the pancreas. He does not discuss the question of the diminution of this ferment in the blood of diabetics (men or animals), but refers to Minkowski, who found the sugar rapidly diminish in blood from a diabetic dog. Professor Seegen suggests that diabetic blood may contain something antagonistic to glycolysis, so that even if Lépine's experiments are correct, they do not necessarily point to a diminution of the ferment in that disease. He holds, therefore, that the explanation of "pancreatic diabetes" has still to be found. Minkowski showed that if a portion of the pancreas (in animals from which it had been extirpated) were transplanted beneath the peritoneum, the diabetic condition is averted, only to appear when the transplanted organ is removed by a further operation. This, as Professor Seegen points out, is comparable with the effect of experiments in thyroid grafting by Eiselsberg, who found that tetany did not occur until the transplanted organ had been excised by a second operation. Morbid anatomy has, however, abundantly shown that in cases of diabetes the pancreas may be quite normal, so that, in fine, upon this question Professor Seegen agrees —and, indeed, has always maintained—that in cases of diabetes there is diminished glycolytic action in the body; but he denies that Lépine has proved this to be due to disease of the pancreas causing a diminished production of a hypothetical ferment.—*London Lancet.*

Disease of the Brain following Simple Operations about the Nose. By Wagner (*Münchener med. Wochenschrift*, 1891, No. 51).—To three cases of operation on the nose (middle turbinate bones) followed by fatal meningitis collected in medical literature, the author adds one which came under his notice. In the case of a man, æt. twenty, suffering from chronic hypertrophic rhinitis, the galvano-cautery was applied to the anterior part of the lower border of the left middle turbinate bone. Three days after there was a smart venous hæmorrhage from the posterior nares, and headache. The bleeding was eventually stopped by plugging. The temperature then went up to 40° C., the pains continued, Cheyne-Stokes' respiration supervened, with stiffness of and pain in the neck, followed by pains in the joints. Death occurred, with meningitic symptoms, thirteen days after operation. A *post mortem* examination was not made.

Direct infection of the brain (sinuses and meninges) can be explained by the anatomy of the parts. Communication of the veins of the middle and superior turbinate bones with the longitudinal sinus, and of their lymphatics with the subdural and sub-arachnoid spaces. How to prevent such complications is difficult, owing to the impossibility of thoroughly disinfecting the nares. Operations on the middle turbinate bones appear to be specially liable to lead to the [illegible]ve results.—(Cramer, C[illegible]

Treatment of Enteric Fever with Chloroform.—Paul Werner (*St. Petersburger Med. Woch.*). The author, after comparing the disease as seen at the present day with the type of twenty years ago, and relating his failure to get the good results he had expected from iodoform, states that he selected chloroform from its well-known antiseptic properties and the recommendation of Behving and Salkososki, and gave it in 130 cases of enteric fever in thirteen months; and as the patients took only its aqueous solution (0.75 per cent.) in doses of one ounce every hour it is hardly surprising that he observed no disagreeable after effects. The meteorism and diarrhœa are said to have speedily disappeared and steady convalescence followed. It is not definitely stated if all recovered nor what was the age of the patients. Amongst children the so-called typhoid fever —febricula—should be recovered from without any medicine whatever, but, as the little ones always like chloroform water, there is no harm in giving it.

Hereditary Idiopathic Athetosis.—This complaint is a rare variety of what was usually called paralysis agitans. M. Raymond, in a discourse on the subject, thus characterizes and distinguishes it. The tremor is observable in the forearm when the patient is recumbent, sometimes also in the upper arm as high as the shoulder. On sitting up the oscillations become more marked, and amount to about five in a second. There is no individual trembling of the fingers as in the athetosis of alcoholism, when each finger possesses a tremor of its own. The number of the oscillations somewhat diminish when the patient takes an erect position after rest. There is a slight tremor of the lower extremities when the patient is in bed if he is made to hold them raised from the bed. There are some fibrillar contractions of the biceps. Walking is well performed; the reflexes are good; there is no loss of common sensation. Carrying a heavy weight, and so producing fatigue, increases the tremor. Alcoholic excess diminishes the trembling, thus again marking off the complaint from the paralysis agitans of alcoholic origin. No abnormal movement of the eyelids, lips or muscles of the face; the tongue is sometimes affected. Heat, emotions, and atmospheric changes (? barometrical) increase the complaint. The hereditary character of the disease is well marked. The disease begins early in life, sometimes about the eighth year, and after attaining a certain intensity does not increase. It is distinguished from senile paralysis agitans by the absence of head movement, and from the hysterical form of the disease by the absence of sensory-moto disturbances.—*Provincial Med. Journal.*

General Purulent Peritonitis with Perforation.—A complete cure in a case of this complaint, generally regarde as certainly fatal, was achieved by Dr. Routier, who opene the abdomen, allowing all the pus to escape and washing the cavity with an antiseptic solution, which was freely used. The wounds were not closed, but free drainage was secured by means of strips of iodoform gauze. Two months after the operation the wounds were found to be completely healed, and the patient resumed his occupation—that of a coal-heaver—and has suffered no inconvenience since.—*Provincial Med. Journal.*

On the Pathology of Dysuria Senilis. By Casper (*Berliner Klin. Wochensch.*, 1892, No. 5).—A few years ago Launois, a pupil of Guyon, put forward the theory that hypertrophy of the prostate was not a local process, but was part and parcel of senile sclerosis of the whole of the urinary apparatus intimately connected with arterio-sclerotic degeneration of the arterial system generally.

[illegible]cal importance of this theory induced Casper to investigate [illegible] He examined the kidneys, bladder, prostate and their vessels, [illegible] the larger arteries, of twenty-eight bodies of men over fift years of age. In the first twenty-four the prostate w enlarged and the aorta atheromatous (arterio-sclerosed in eight cases only was there arterio-sclerosis of the vesse of the kidneys and of the vesical arteries in the walls of th bladder; in nine cases this condition was present in th small arteries of the bladder and in the prostatic and per prostatic vessels. In two cases only this condition was foun in the kidneys, bladder, and prostate simultaneously. I the remaining twenty-two cases it affected either bladde and prostate, kidneys and prostate, or kidneys and bladde The four other cases presented endo- and peri-arteritic processes in the vessels of the urinary apparatus, but the prostate was not enlarged.

Casper cannot, therefore, accept Launois' theory. H admits that hypertrophy of the prostate is frequentl accompanied by changes in the vessels, but he holds it is condition independent of arterio-sclerosis.—(Müller, *Centralblatt fur Chir.*, No. 14, 1892.)

Pharyngeal Tuberculosis.—At a meeting, February 1 1892, of the French Society of Dermatology and Syphilography, M. Jullien presented a woman who was the subjec of pharyngeal tuberculosis. The disease had been acquired by cohabitation. Such a rare mode of infection is worth mention. The woman had had for several months relations with a tuberculous individual. Upon the pharynx were seen distinct ulcers, in which M. Jullien discovered the bacillus of Koch.—*Le Progrès Médical*, February 13, 1892 *Medical Bulletin.*

Obstinate Hiccough.—Dr. H. M. Shallenberger, of Rochester, Pa., recommends fluid extract of physostigma in doses of 4 to 8 drops, pushed to the point of causing toxic symptoms.—*Medical Record.*

MISCELLANY.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from June 18, 1892, to June 24, 1892.

Major John S. Billings, Surgeon U. S. A., granted leave of absence for one month and fourteen days, with permission to go beyond sea.

Capt. William B. Banister, Asst. Surgeon U. S. A., is granted leave of absence for one month, to take effect on or about July 1, 1892.

ORIGINAL ARTICLES.

ADDRESS ON THE OBJECTS OF THE AMERICAN MEDICAL TEMPERANCE ASSOCIATION,

AND ON THE PHYSIOLOGICAL AND THERAPEUTIC DIFFERENCES BETWEEN THE CARBO-HYDRATES CONSTITUTING PROXIMATE ELEMENTS OF LIVING VEGETABLE AND ANIMAL BODIES, AND THOSE RESULTING FROM BACTERIOLOGICAL OR RETROGRADE ACTION.

Delivered at the Annual Meeting in Detroit, June 9th, 1892.

BY N. S. DAVIS, M.D., LL.D.,
PRESIDENT OF THE ASSOCIATION AND DEAN OF THE NORTHWESTERN UNIVERSITY MEDICAL SCHOOL, CHICAGO, ILL.

Ladies and Gentlemen:—We are assembled to note the first anniversary of this Association, which was organized in Washington, D. C., May, 1891. The objects had in view by those who participated in its organization as declared on that occasion were, "to advance the practice of Total Abstinence in and through the medical profession, and to promote investigation as to the action of alcohol in health and disease; and to form a bond of union among medical abstainers all over our country." That those three objects are of sufficient importance to challenge the attention of every well informed and unbiased member of the profession, must be admitted by all. Especially is this true, if we consider the fact that more than $800,000,000 are annually paid for alcoholic drinks, fermented and distilled, by the people of this *country; over $700,000,000 by the people of Great* Britain; and nearly in the same ratio by all the nations occupying the Continent of Europe; and all this without returning so much as a single cent to the consumers who pay the money, or a pound of bread for their families. If we also consider the fact that all our highest judicial authorities and social economists attribute much more than half of all the pauperism and crime, in the same countries, *to the use of those drinks*; while the highest authorities in our own profession freely admit that a large percentage of the sickness and mortality is traceable to the same source, we will be compelled to admit that there is no other topic more imperiously demanding the candid, persistent and thorough investigation by every practitioner of the healing art, than that which relates to the real influence of alcohol directly upon the living human system and indirectly upon the collateral interests of the race.

To make such investigations accurately and reliable, the investigator must himself be free from the deceptive and perverting influence of the alcohol upon his own brain and blood. In the language of our excellent Code of Ethics: "It is incumbent upon the faculty to be temperate in all things, for the practice of physic *requires the unremitting exercise of a clear and vigorous understanding; and in emergencies,* for which no professional man should be unprepared, a steady hand, an acute eye and an unclouded head may be essential to the well being, and even *life of a fellow creature." Hence, our by-laws* require the practice of total abstinence from alcoholic drinks by the members of this Association, although they place no restrictions upon the conscientious use of alcohol in the treatment of disease. To determine more accurately the origin, nature, physiological effects, and therapeutic uses of alcohol, and to diffuse a knowledge of the same, both in and out of the profession, is the paramount object of our organization. As an Association we have nothing to do with the political parties and questions of the day whether of prohibition, high license, low license, protection, free trade or reciprocity. Our work is one of strict scientific inquiry and investigation. Professor Schmoller, the economist of Germany, says: "Among our working people the conditions of domestic life, of education, of prosperity, of progress, or of degradation, are all dependent on the proportion of income which flows down the father's throat. The whole condition of our lower and middle classes, one may even without exaggeration, say the future of the nation, depends on this question." As the same may be said with equal truth concerning our own people, it certainly becomes us as the professional guardians of the public health, to ascertain more certainly the nature and effects of those drinks that "flow down the father's throat," and which carry with them the income, on which depends the domestic happiness, the education, the prosperity and much of the health of the whole community. It is hardly necessary to say that the one essential ingredient in all the "drinks" here spoken of, whether fermented or distilled, is alcohol. It is not found as a proximate element in living organized bodies, either vegetable or animal, but is exclusively the product of bacteriological action on glucose or saccharine matter, constituting the process known as vinous fermentation. In other words the alcohol is an effete toxic product resulting from the action of the microörganism known as the torula cerevisiæ, of Turpin, on sugar or glucose, and is composed of C_2H_6O. It is therefore chemically a pure carbo-hydrate, and early in the progress of analytic and organic chemistry, it was unfortunately classed by Baron Liebig with those carbo-hydrates resulting from vegetable growth or nutrition, starch, sugar, gum and cellulose, as supporters of combustion or respiratory food when taken into the human system. Such classification was not founded on the results of any scientific investigations *showing that the* actual effects of alcohol, starch, sugar, etc., when taken into the living system, were similar, but solely on the fact that they were all composed of the same ultimate elements, carbon, hydrogen and oxygen, in such proportion as to admit of further oxidation outside of the living body.

And as such oxidation or combustion was accompanied by the evolution of heat, it was assumed, without experiment or proof, that all these carbohydrates were oxidated in the living system, and were active supporters of respiration and animal heat, while the various organized animal tissues were developed and nourished from the nitrogenous proximate elements of food. The simplicity of such a classification of foods and animal tissues, aided by the high authority of Liebig, caused it to be universally accepted and thoroughly incorporated into both medical and general literature, where, in the public mind at least, it still remains; and is a fair illustration of the danger or fallacy of assuming that similarity of chemical composition is proof of similarity of action when taken either as drink, food or medicine.

From a somewhat extended investigation of the subject, I think it may be stated as a general law, that all the orders of animal life are dependent for their development, growth and nutrition, upon materials resulting from either vegetable or animal growth. Certainly none of the higher orders of animal life assimilate and appropriate for the growth or repair of their structures and the support of their physiological processes, inorganic materials not previously combined under the formative or vitalizing influence of vegetable or animal life. It may be further stated as an equally general law, that the products of retrograde metabolism or tissue metamorphosis as presented in the excretions and eliminations from living bodies, both vegetable and animal, are not only not capable of being used as food, but are either inert or positively toxic if retained or reintroduced into the living body. Hence we have a clear and most important distinction between such carbohydrates as starch, sugar, gum, cellulose and dextrin, resulting from vegetable and animal nutrition, and the alcohols, which result solely from retrograde metamorphosis or bacteriological excretion, usually termed fermentation. And instead of acting alike as respiratory or indirect food, as has been claimed so long, all the strictly scientific investigations of the last half century have proved their action upon the structures and functions of the living body to be as diverse as their origin. Thus the carbo-hydrates of the first class named, starch, sugar, gum, etc., when taken into the healthy stomach, readily undergo such digestive and assimilative, or molecular changes that their identity is not recognizable in either the blood or tissues of the healthy animal, and the products derived from them produce no unnatural excitement or disturbance in any of the functions and processes of the living body. Though taken in proper quantities daily from year to year, they create no craving or morbid appetite for more; and when the quantity taken at one time is excessive, such excess is rejected ith the ordinary fæcal matter of the intestines.

But the alcohols constituting the second class un- o no such digestive or assimilative changes in mach or digestive apparatus. If the ordinary alcohol is taken into the living stomach un- d absolutely pure, it acts directly upon the h which it comes in contact as a destruc- ve poison, and speedily destroys the life etables and animals when brought in n them. When largely diluted with water, e various fermented and distilled liquors, nto the stomach, it is rapidly imbibed, without change, and carried directly into the blood, and with it, into every tissue and organ of the body, as has been demonstrated by the application of reliable tests many hundred times. More or less of it also soon reappears in the excretory secretions and eliminations of the lungs, skin and kidneys, like other foreign or non-assimilable materials. While retained in the blood and in contact with the tissues, the alcohol modifies in a marked degree the sensibility of the nervous structures, and also the molecular or metabolic changes concerned in nutrition, disintegration and sensation. If taken daily for a considerable length of time, it invariably creates a morbid appetite or craving for steadily increasing quantities, and sooner or later establishes degenerative changes in nearly all the organized structures of the body. It is obvious, therefore, that there is actually no similarity or analogy, either histological or physiological, between the carbo-hydrates of vegetable and animal growth and those derived from bacteriological or putrefactive fermentation. And the time has fully come when the purely theoretical, and most mischievous error of grouping them together as respiratory and force generating food, should be corrected in all our literature and eradicated from the public mind. Half or three-quarters of a century since, when alcohol was placed at the head of the list of respiratory foods by the chemico-physiologists of that day, it was claimed that when taken into the living body it readily combined with oxygen, and was resolved into carbon dioxide and water, with the evolution of heat; and hence it came into almost universal use as a supposed stimulant and promotor of animal heat. Step by step, however, investigations carefully devised and faithfully executed, have not only demonstrated this supposition to be erroneous, but they have equally demonstrated the real action of alcohol in the living human system to be that of an active anæsthetic, directly diminishing cerebral and nerve sensibility and muscular action; a retarder of the internal respiration, by which oxygen is carried from the pulmonary to the systemic capillaries; and a sedative or retarder of the molecular or metabolic changes in the tissues and secreting structures of the body. These several propositions have been so fully sustained by the direct experimental investigations of Prout, Böcker, myself, Richardson, Anstie, Hammond, Harley, Sidney Ringer, Martin, H. C. Wood, Lauder Brunton, Dubois, Reichert and many others, that it would be superfluous to quote them in detail. There are, however, still many, both in and out of the profession, who claim that the alcohol is an anæsthetic only when given in large doses; while if given in smaller doses and repeated at suitable intervals, they claim it acts as a stimulant and tonic, especially on the cardiac nerves. The incorrectness of this claim is completely demonstrated by the investigations of Drs. Ringer and Sainsbury, Professors Martin and H. C. Wood.

The experiments of Sidney Ringer and Harrington Sainsbury were instituted for the purpose of determining the relative strength of different alcohols as indicated by their influence on the action of the heart of the frog. In closing their report on the subject they say: "By their direct action on the cardiac tissues these drugs (alcohols) are clearly *paralyzant*, and that this appears to be the case from the outset, no stage of increased force of contraction preceding."

The experiments of Professor Martin, of Johns

Hopkins University, were performed on the dog, and he states the results obtained as follows: "Blood containing ⅛ per cent. by volume of absolute alcohol has no immediate action on the isolated heart. Blood containing ¼ per cent. by volume, that is, 2½ parts per 1,000 of absolute alcohol, almost invariably remarkably diminishes, within a minute, the work done by the heart; blood containing ½ per cent. always diminishes it, and may even bring the amount pumped out by the left ventricle to so small a quantity, that it is not sufficient to supply the coronary arteries."

Professor H. C. Wood, of the University of Pennsylvania, also executed his experiments on the dog, and in his address to the International Medical Congress at Berlin, 1890, states his results as follows: "An 80 per cent. fluid (alcohol) was used, diluted with water. The amount injected into the jugular vein varied in the different experiments from 5 to 20 cubic centimetres, and in no case have I been able to detect any increase in the size of the pulse, or in the arterial pressure, produced by alcohol, when the heart was failing during advanced chloroform anæsthesia. On the other hand, on several occasions the larger amounts of alcohol apparently greatly increased the rapidity of the fall of the arterial pressure, and aided materially in extinguishing the pulse rate." That alcohol exerted, not only a general anæsthetic effect upon the nervous system, but also a special or direct paralyzing influence on the cardiac and vaso-motor nerves, strictly parallel with that produced by chloroform and ether, was clearly shown by R. Dubois in 1883. And the editor of the department of experimental therapeutics in the fifth volume of the Annual of Universal Medical Sciences, 1892, in referring to the review of the work done by nearly all those who have engaged in experimental investigations regarding the effects of alcohol on the living system, by E. MacDowell Cosgrove, truly says: "Contrary to what has been and is supposed, it is found from all these researches, that small doses of alcohol, from the first, produce a narcotic rather than a stimulating effect." And he adds that all the observers except one, had "also found that alcohol in small doses diminished the amount of carbon dioxide exhaled." It is thus shown, by the direct experimental researches of the most eminent men in different countries, aided by all the instruments of precision invented in this period of active scientific progress, that alcohol in the living system actually diminishes the sensibility and action of nerve structures in direct proportion to the quantity used. An ordinary regard for scientific accuracy, therefore, demands that it should be classed as an anæsthetic or narcotic, and in no sense as a stimulant or tonic. In studying further the mode by which alcohol produces its effects while in the living human system, it is necessary to appreciate the full import of the following propositions:

1. All nerve sensibility and force, and all natural molecular or metabolic changes, nutritive, secretory, and disintegrating, taking place in the living tissues, are absolutely dependent on the presence and movement of blood containing its natural proportion of oxygen.

2. The oxygen needed in the blood is received from the pulmonary air cells by the hemaglobin and serum of the blood and in them conveyed to the systemic capillaries, where it comes in contact with, and exerts its influence on, every cell and structure of the body.

3. Alcohol at ordinary temperatures of the air, or even of that of the living human body, manifests but a very feeble affinity for oxygen, but does manifest a very strong affinity for water, albumen and hemaglobin, acting upon them readily at all ordinary temperatures.

If, therefore, alcohol sufficiently diluted to permit its circulation in the blood, should be introduced, either by the stomach or any other method, instead of uniting with the oxygen, it presents its superior affinity for the hemaglobin and serum albumin, and thereby directly interferes with their reception of more oxygen from the pulmonary air cells. It is thus that the presence of the alcohol hinders the hemaglobin from being converted into oxy-hemaglobin in the pulmonary capillaries, and in the same ratio diminishes the amount of oxygen conveyed to the systemic capillaries; and in the same ratio, also, the nerve sensibility and metabolic changes diminish. This affords a full explanation of the facts now admitted by all who have carefully studied the subject, namely, that the presence of the alcohol retards both nutritive and disintegrative changes, diminishes excretory products and temperature, and lessens nerve sensibility and force.

An explanation of these admitted facts has been hitherto, and still is, sought for on the supposition that the alcohol simply unites with oxygen of the blood and thereby prevents or diminishes the action of the latter on the tissue elements of the body, and yet generates heat and some kind of force. The fatal defect in this old combustion or oxidation theory is, that no investigator has been able to find the legitimate products of such oxidation. So far as is known the oxidation of alcohol resolves it into either aldehyde, carbon dioxide and water, or acetic acid, and evolution of heat. Consequently, if alcohol underwent oxidation in the system some increase of one or all of these products should have been uniformly found, either in the blood, the exhaled air, or in the other excretions. But instead, the most accurate and numerous investigations show less carbon dioxide in the exhaled air, less temperature of the body, and neither acetic acid nor aldehyde in the blood.

And yet the puzzled investigators turn and say that, inasmuch as the alcohol disappears in the system and cannot be all regained from the secretions and eliminations in a limited time, it *must* have been oxidized and converted into some kind of force. But what force? Certainly not nerve force, mental force, muscular force, heat force, or metabolic force; for all of these are directly diminished by its presence. The only force found operative in the case, is the superior affinity of the alcohol for the hemaglobin, albumin, and water of the blood; and its toxic power to so modify their molecular condition and properties as to diminish their efficiency in receiving and conveying the oxygen from the pulmonary to the systemic capillaries, and thereby impairing all the vital processes in which the presence of oxygen is required.

This view also affords a rational explanation of the numerous pathological changes everywhere recognized as resulting from the habitual use of alcoholic drinks, even in the most moderate quantities. These changes were well exposed in the celebrated discussion on chronic alcoholism by the Pathological Society of London, only two years since, and are easily found on the pages of our medical literature.

It enables us also to see clearly the philosophy or *rationale* of those illusions and delusions that have been imposed upon the human mind by the use of alcohol in both health and disease through all the generations of the past. Thus, a moderate dose in health by its anæsthetic effect on the nerve cells of the brain lessens the individual's consciousness of cold or heat, of weariness or despondency or weakness, and he is deluded with the idea that it had warmed and cheered and strengthened him, when it had done neither; but instead, had simply diminished the acuteness of his own perceptions while the evils continued in full force. So in the progress of disease, its use generally has the same anæsthetic effect, causing the patient to complain less, rest more, and often say he feels better, but it neither removes the exciting cause, nor corrects the morbid processes constituting the disease, nor increases the activity of the metabolic changes of either nutrition or elimination. Nor is this all. For in the same proportion as the alcohol diminishes the internal distribution of oxygen and thereby acts as a so-called conservator of tissue, it still more actively interferes with the katabolic processes by which the natural excretions are maintained and foreign disturbing elements are eliminated, and consequently it prolongs the morbid processes, favors molecular degenerations, and increases the ratio of mortality. Clinical facts and cases could be cited in abundance, illustrating and sustaining the correctness of the foregoing views, did my time permit. I will, however, at present only add for your consideration the following questions:

1. If the physiological standard of health requires a natural degree of sensibility of the cerebral hemispheres and the internal distribution of oxygen in natural quantity, and the presence of alcohol diminishes both in direct ratio to the quantity taken, how is it possible for persons in health to use it without injury?

2. If the alcohol, while in the living system, does thus diminish the sensibility of the nerve structures and retard the internal distribution of oxygen, is it not a true anæsthetic and organic sedative, and, therefore, adapted to the treatment of only a very limited number of morbid conditions presented in the progress of disease?

3. Is it not true that all the fermented and distilled alcoholic liquors are genuine toxic products of bacteriological cultures, and ought we not to uniformly designate them as such, instead of continuing to delude ourselves, our patients, and the public generally by calling them tonics, stimulants or indirect food?

NEW AXIS-TRACTION OBSTETRIC FORCEPS.

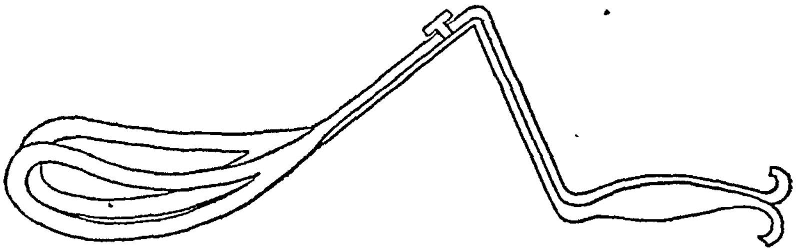
Read before the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, at Detroit, Mich., June 7, 1892.

BY WILLIAM B. DEWEES, A.M., M.D., UNIV. OF PA.,
OF SALINA, KAN.
Vice-President of the Pan-American Medical Congress for Kansas, Ex-President of the Golden Belt Medical Society of Kansas, Member Western Association of Obstetricians and Gynecologists, Fellow American Academy of Medicine, etc., etc.

As progressive obstetricians, following Nature's guidance at all times, we are ever directed by the truism, that "real wisdom is always simple."

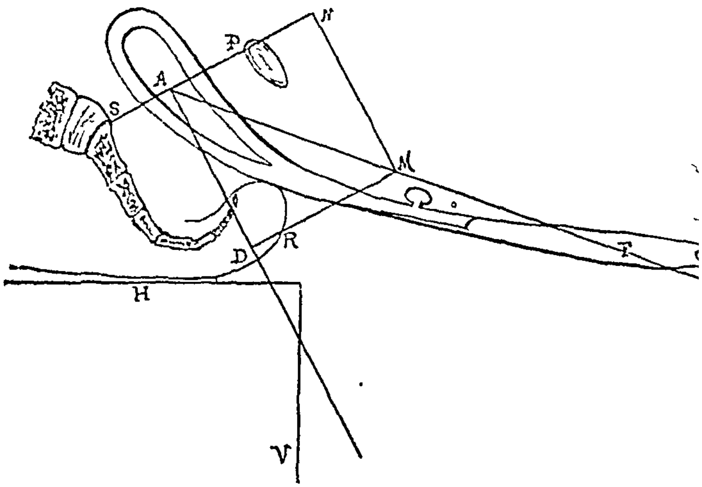
With regard to the use of the obstetric forceps, it may id truthfully that the principle of axis-tra conceded by all thoughtful and observing practitioners to be correct. That the day is already dawning when the authorities will hold that no woman should be delivered by instrumental aid, except by axis-traction. But the various ideas advanced for its production are, however, conflicting, and some are even fallacious.

Being convinced, after timely observation and experience, that the desideratum to fulfil the *rationale* of the axis-traction principle was still wanting, I endeavored to supply the same. I succeeded in having Geo. Tiemann & Co., of New York City, make a forceps after my own idealization, which I now have the pleasure of presenting before this august body. The only important new feature is the construction of the perineal curve, and providing the same in the handles which serve for *axis-traction*. It is an aseptic, simple, efficient and economic instrument.



DIMENSIONS.—Length of forceps, 16 inches. Length from lock to tips of blades, 9 inches. Length from lock to perineal curve, 1 inch. Length of perineal curve, 5 inches. Length of axis-traction handles, 5 inches. Average width of blades, 1¾ inches. Greatest width between blades when closed, 2½ inches. Width between tips of blades when closed, ¾ inch. Weight, 20 ounces.

To demonstrate more clearly that the action of this forceps is in strict accord with the acknowledged axis-traction principle, I beg leave to first call your attention afresh to the classical demonstration of the axis-traction principle, as given by Tarnier.

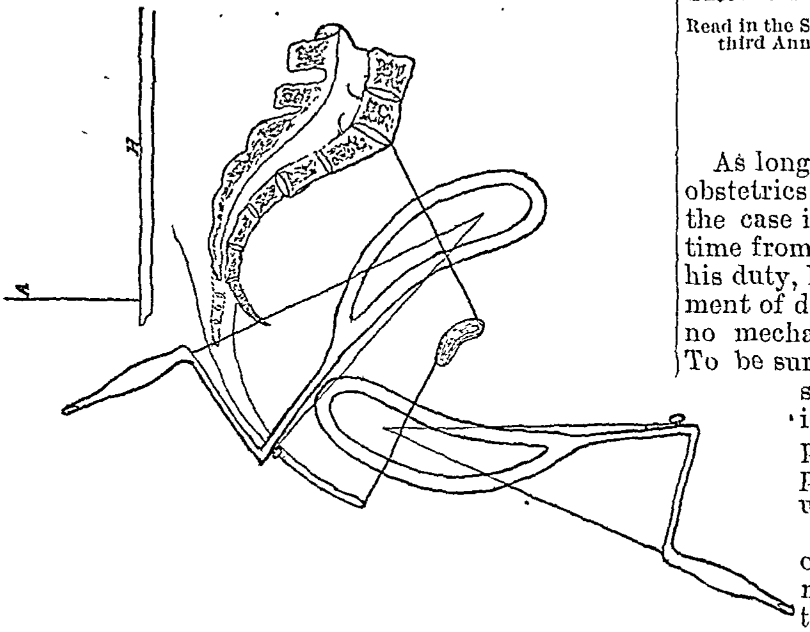


TO ILLUSTRATE AXIS-TRACTION. (Tarnier after Barnes.)
H. V.—Horizontal and Vertical lines of a table. S.—Sacrum. P.—Pubes.

"The figure represents an application of the forceps at the brim. The line A B indicates the axis of the opening which the head must traverse, and therefore the direction the tractions must take to be correct. But when the operator pulls upon the handles of the forceps, the tractions he makes are converted into a force represented by the line A F. Supposing that these tractions equal 40 kilograms, and they be represented by the distance A M, and we construct upon this line A M the parallelogram of forces A D M N, we find that the traction A M is decomposed into two forces—the one, A D, which tends to lower the head in the direction of the axis of the brim; the other, A N, representing a vicious pressure which falls upon the pubes. Now, the lines A M, A D, A N present different lengths, which are expressed by the numbers 10, 30 and 26, in round numbers. Therefore, in pulling upon the handles of the classical forceps with a force of 40 kilograms, one tends to lower the head in the direction A D with a force of 30 kilograms only, whilst involuntarily the pubes is subjected to a vicious pressure of 26 kilograms. It must be understood that in this calculation I have taken into account simply the force and the pressures arising out of the act of the operator, neglecting those which proceed from the natural action of the mother's tissues."

Barnes, in commenting on this, voices the logical conclusion when he says: "He thus demonstrates that it is impossible to pull in the axis of the upper strait or brim, and to avoid vicious pressure by grasping the handles of the ordinary forceps. Those who object to Tarnier's forceps insist that, by the well-known manœuvre of pulling on the handles with one hand, and at the same time pushing back upon the shanks with the other, the direction of the traction is changed to that of the axis. We are convinced from long practice and many close observations, that the correction thus obtained is inconsiderable, and that Tarnier's demonstration is true. Tarnier next applies a like method of demonstration to the action of the ordinary forceps in the cavity and outlet, showing that in these cases also there is waste of force and vicious pressure."

With your minds thus refreshed, let me now call your attention to the following diagram, which will, I trust, demonstrate to you with sufficient clearness as to convince you that this forceps fulfils, in the simplest manner, the desideratum of an ideal axis-traction instrument in strict conformity with the *rationale* of the axis-traction principle.



To Illustrate Axis-Traction with the new Axis-Traction Forceps.
H. V.—Horizontal and Vertical lines of a table.

With the patient placed in the left lateral (English) position, obliquely across the bed, with the nates brought to its verge, and by the use of this forceps, it is claimed:

1. That axis-traction is made perfect, easy and simple.

2. That axis-traction at the superior strait is perfect, and so continues during the entire passage of the fœtal head, following the curve of Carus from the brim to the outlet, with ease and safety.

3. That the axis of the blades of this forceps lies constantly parallel with the axis of the parturient canal as the head descends; thus enabling the accoucheur to fulfil a most important aim in forceps operations, namely: to deliver with a minimum amount of force.

4. That the operator is enabled to seize the head more advantageously at the brim, and the facility with which the head can be aided to descent in the axis of the superior straits, as well as to follow the axis of the pelvis, would seem scarcely possible to one accustomed only to the ordinary forceps.

5. That it is easy of application, and in its triple character—having a moderate head curve, a moderate pelvic curve, and a decided perineal curve (the latter is provided in the handles which serve for traction)—it has all the advantages of axis-traction with plenty of power and perfect control, and with the simplicity of the ordinary forceps.

6. That it does away with the complicated, cumbersome and expensive attachments of the Tarnier and other models. The indicator is constantly in the sentient hands of the operator, who thus at every moment knows, through his *conscience musculaire*, the direction of traction as well as the resistance. Thus preserving intelligent observation of the progress of labor and regulation of the forces employed, which alone can be done by the use of the hands in executing traction and extraction.

THE MANAGEMENT OF LINGERING LABOR.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual meeting of the American Medical Association, held at Detroit, June, 1892.

BY GEO. C. MOSHER, M.D.,
OF KANSAS CITY, MO.

As long as the physician continues the practice of obstetrics as at present the usual custom, allowing the case in hand to consume the greater part of his time from the hour it is first seen until he finishes his duty, having delivered the patient, the management of delayed or lingering labor where there exists no mechanical obstruction must prove a bugbear. To be sure there are physicians who do not, as they say, "waste their time" in this tedious fashion, but in point of fact the number of practitioners of my acquaintance whose practice is to leave the parturient woman until actually needed is very small indeed. However anxious he may be to answer other imperative calls, however tired he may be and however so much he may feel that his services are not absolutely required for the time being, still the careful accoucheur does not feel at ease unless within call of his patient.

This being the case it is only natural that many expedients have been resorted to, in order to hasten the desired result. When we shall have reached the Utopian age where we can trust our patient to the care of a conscientious, obedient, intelligent and discreet nurse upon whose judgment we can rely to conduct the case in the interim between the first examination and such time as the physician's skill is ultimately necessary, then this feature of the case will not need be discussed. But this will require an education vastly superior to that now possessed by the average nurse, and also of the patient, and more especially of her friends and over solicitous neighbors, as well.

In the mean time the plain uncomplicated case of lingering labor drags itself wearily along, and what means are best for its management in the interests of the mother, the child and the doctor, the three parties especially concerned? Elaborate treatises have been written upon the more complicated obstetric operations, but this topic which more frequently than abnormal presentation or pelvic deformity or any other surgical feature of obstetric art, is se, an [illegible]nted for consideration, is, as a rule, but touch litera [illegible]htly ilosoph.

upon in passing from normal labor to that requiring mechanical interference. In no situation is the young obstetrician so uncomfortable as to have assured an anxious family that everything is all right and promised a speedy delivery, then have the pains die out and leave him for hours in a state of uncertainty.

Lingering labor is generally understood to signify a labor where the head presenting normally, the case occupies more than twenty-four hours between commencement and termination, estimating from the beginning of true uterine action. In regard to the effect on the strength of the patient, however, it is not usual that any considerable effort has been made or great exhaustion suffered previous to the rupture of the membranes. Hence in calculating the danger of injury to the soft parts it is sufficient to take into account the time after the escape of the liquor amnii, as the volume of the fluid acting as a cushion renders it impossible for any alarming pressure to be experienced.

Cases related where women have been in labor for ten days or two weeks are not worthy of consideration, being as a rule but exaggeration of the false pains suffered previous to any ordinary labor. In the case of long delayed labor it is ordinarily found that the patient has been debilitated by some previous illness, or if a multipara, the mother of a large family, the uterus fails to act with its accustomed vigor, being in this instance a reversal of the physiological law that muscular energy and tone are increased by exercise. Here the rhythmic character of the contractions is lost and feeble irregular pains are met with, where a roomy pelvis and good dilatation are found and every indication apparent that the powers of nature alone are wanting.

If we remember that in normal labor there is a distinct period of rest between the pains which permits the nervous system to recover itself after the contraction, it can be readily seen that if the pains are constant, without interval of relaxation, the tone of the muscular fibres must be finally exhausted and rigid os likely result as is so often seen in primiparæ where delivery is thus impeded.

From the earliest times efforts have been made to hasten delivery and some of the means are still extant which have become classical in their antiquity. Borax, the virtues of which we frequently hear through midwives and nurses, has had its advocates since the days of the ancients. Cinnamon, fox glove and other similar means, the interest in which at the present day is merely of an historical character, are in the same category as borax. The Asiatics had a favorite plan of treatment, that of tying a piece of tiger's skin over the left thigh of the parturient woman to promote uterine action. Lewis and Clark in their voyage up the Missouri mention the happy result of a dose of twenty grains of powdered rattlesnake tail in the case of an Indian squaw who was a servant in their party and whose labor was unduly prolonged. This same remedy was highly esteemed among African tribes. There is more method in the practice of Mexican Indians who have a tripod prepared under direction of the midwife who is to officiate, according to Engellmann, and from the top of this apparatus a rope dangles; this the patient grasps with her hands and the attendants take turns of encircling her body with their arms and pressing downward until she becomes worn out, then the rope is tied under the arms and the same squeezing process kept up until the patient is delivered or dies, the doctor never lets up until something is accomplished.

Among the Thomsonians, a school of physician which flourished in the early part of the present century, in our own country, the act of sneezing was invoked to hasten abdominal contractions and some amusing stories have been told of their success and the discomfiture of regular physicians when their practice came in conflict. This plan was called "quilling" and consisted in filling a goose quill with snuff, inserting the quill into the patient's nostril and blowing; often with a sneeze or two the babe was born.

At the present time it is the rule to learn the cause of the delay, to carefully exclude all cases of deformed pelvis, of unusual disparity between the fœtel head and the maternal parts and to look carefully to the rectum and bladder being emptied, before calling the case one of delay, simply, then an effort is made to treat it on physiological principles.

Among the remedies proposed to increase weak pains, and to induce pains where they are failing, warm teas and various drinks are most commonly resorted to among nurses and certainly these can do no harm where they are well retained and perhaps, by brightening up the patient may do good by encouraging her to renewed effort where her courage is failing. At any rate it satisfies her friends that something is being done to relieve her and hasten her delivery. Unless there is great prostration and dangerous weakness, I do not consider stimulants indicated, still a popular reputation that is enjoyed by a cup of warm toddy renders it of such frequent use that it may be allowed occasionally where there is no contra indication. However, the benefit derived is questionable unless the condition of the patient, aside from her labor pains seems to require stimulation.

To the use of ergot previous to the expulsion of the placenta, I am thoroughly opposed. In several cases where its employment was observed the death of the fœtus followed, and after the fœtus has been delivered and ergot used to bring down the placenta, hour glass contractions have been set up, and added to the delay, rather than helping the matter. Where Créde's method is accurately followed other means are seldom required in delivering the placenta.

To show how much the practice of physicians is to run to fashions, I may quote Mitchell who in 1828 wrote that, "In twenty years the use of ergot becoming thoroughly introduced the forceps would be known only in name and save in rare cases where Cæsarean section was formerly recommended there would be no need for interference in midwifery."

To be sure there are good practitioners who as a regular plan follow the administration of ergot in all cases, freely, and seemingly to me, recklessly, but its dangers and disadvantages of producing clonic contraction, compression of the cord, occasionally rupture of the uterus, etc., are so grave that its use has not seemed justified.

Dr. Beatty in the *Dublin Quarterly Journal of Medical Sciences*, August, 1850, advocated the combination of chloroform and ergot to mitigate the evils of their separate employment, citing numerous cases to prove his position. Quinine as an oxytoxic has been highly praised by Fordyce Barker and in doses of 15 grains of the bisulphate has apparently been of benefit in some cases in which I have used it. Hot water by the douche thrown against the unyielding cervix is a valuable aid. The application of hot water cloths, corn meal or bran poultices and similar external stimulants are to be commended, and excitation by slapping the abdomen with a wet towel will occasionally be followed by a good pain. The plan recommended by Zweifel of pressure upon the breech through the abdominal wall, using the left hand and attempting with the right hand, also externally, to aid the head in the direction of the pelvic canal is often of surprising help, aiding the head in rotation and fixation here as in other obstetric operations. Intelligent changing of the patient's posture is often followed by pronounced advance of the fœtal progress.

My rule has been to use chloral in lingering cases where it is not contra-indicated ordinarily, by rectal injection. In some cases its use has so quieted the nerves that a period of repose followed which gave the patient renewed zeal and the happy effect of a speedy termination of the labor. Sometimes an hypodermic injection of morphine is indicated combined with a small dose of atropia, where the nervous system is racked with violent pains which as they say " do not bear right," where a rigid os is found and a history of several hours fruitless suffering. This is most often successful in primiparæ where the pains begin robust and regular but finally fade and become irregular and inefficient.

The use of chloroform is advisable later on in the labor when the head presses firmly on the soft parts and the danger is that the perineum may suffer from the sudden accession of energy liable to come up as the final effort is being made. Earlier it is apt to cause the pains to die away for the time being and in a number of instances that are recalled the use of forceps was demanded because of this condition being induced because the persistent entreaties of the patient for chloroform were complied with. When all other means have been exhausted and the *caput succedaneum* can be distinctly felt, filling up the orifice of the vulva, the parts becoming hot and perhaps swollen; the patient feverish, pulse quickened and the general condition indicates that her force is spent, the final resort is the forceps.

I am well aware that many practitioners do not wait for these conditions to arise but put on the forceps early in the labor, but I want to make a plea for conservative action in this event. Give nature a chance before interfering. The more experience gained the less and less frequently do I find forceps necessary. Many a time mother nature has come to reassert herself when it seemed that instrumental delivery was inevitable. I recall a case some years ago where I had spent the night at a case of lingering labor and at five o'clock in the morning I told the patient that she must be delivered with instruments. I went across the street to ask my friend Dr. Porter for his forceps and found he had left them at his office. Returning to the house to send a messenger for my own case, I was most agreeably surprised to find good labor pains had set in, and before the forceps arrived the case was terminated without mechanical aid. The moral effect on the patient's mind had evidently been sufficient to assist her. This result has so often happened that it has become a habit to speak of instruments to that class of patients that one always thinks, now if she only would try once more she might get through. There are authorities who say " Put on the forceps in all cases where the membranes being ruptured the labor is not terminated in two hours," but there can be *no iron clad* rule regarding these cases any more than in case of firm membranes to say when we should rupture the sac. Each case being a law unto itself, excepting the general rule that no patient should be allowed to go on to complete exhaustion before energetic means are adopted for her relief.

The interests of the child are as a rule identical with those of the mother and the means proposed to secure her safety happily preserve the offspring as well. In advocating conservatism in using forceps it is only conservatism, not timidity, that is asked. Many lives are saved by intelligent use of forceps where formerly the same class of cases proved fatal to the child and perilous to the mother. The well known case of Princess Charlotte, of England, whose historic and unhappy labor was allowed by her distinguished attendants to drag along from simple inertia of the uterus two days after she should have been delivered offers a striking illustration of the want of such interference. She could have been, beyond question, saved by prompt forceps delivery and this would perhaps have changed an entire dynasty in Great Britain.

In a paper read at the Birmingham meeting of the British Medical Association, 1890, Dr. W. S. Playfair, the distinguished London obstetrician, pointed out some of the means which he considered best adapted to certain phases of labor, and I was much interested in the discussion which was participated in by many of the celebrated men of Britain, and was especially impressed with the thought that the lights of the obstetric world are as much at variance upon those points as would be shown by a comparison of the views of our own confreres.

Dr. T. More Madden, of Dublin, claiming to control the largest obstetric clinic in Great Britain, said his invariable rule was to give ergot in every case of lingering labor, in doses of three to four drachms of watery extract and to fortify this with a hypodermic injection of ergotine. Dr. Murdoch Cameron, of Edinburgh, related how he came to regard opium as a sheet anchor in these cases. He had left with a patient two vials, one containing laudanum, the other fluid extract of ergot and the nurse had given the laudanum at regular intervals instead of the ergot as directed. This, by quieting the nervous system brought on good labor and a case that he had expected to continue for a long time was brought to a close in three hours. Since then it was his plan to carry a bottle of two grain opium pills in his pocket and upon being called to a case of labor, he gave his pills at two hours intervals with the assurance that the case would be soon over or he could go home and get an all night's rest as far as that particular patient was concerned. Others advocated strychnine by hypodermic injection, Barnes' uterine dilators, gelseminum, electricity and a host of novelties in the way of therapeutic aids to delivery.

It is with a good deal of diffidence that I venture to bring this subject before the Section at this time when papers are being presented teeming with erudition and modern methods of procedure. No new theory has been advanced and no especial hobby championed, the greatest good hoped to be accomplished by a general *resumé* of the field is to draw out the opinions of these gentlemen present who may be interested in obstetrics or who may be familiar with its practice.

Dr. Shelton, of Maryland, in discussing the paper of Dr. Mosher, considered that the failure of the woman to bear down in cases of retarded labor is often the cause of the delay, and that this failure is occasioned by the sensitiveness of the parts. To relieve this he applies cocaine and boracic acid locally, or gives chloral and bromides internally.

Dr. C. R. Reed, Middleport, Ohio, said in interfering in delayed labor, much depended on the cause of the delay. He now very rarely waits two or three hours after the os is dilated. He uses the forceps in primipara in three cases out of four, and has not observed that the perineum is ruptured any oftener when the forceps are used than otherwise. I know I am not borne out by the authorities. I care nothing for that. I know that many cases might have been delivered without the aid of the forceps, but I have never regretted the use of the instruments.

Dr. Sell, New York, related a case of non-rotation of the head in the Vienna Hospital,

Dr. Don, Lewiston, Mich., related two cases where the ammiotic fluid remained to a large extent, and assisted rotation. If the uterus seizes the head tightly and you attempt to rotate the head in the pelvis you may fracture the neck.

Dr. E. G. Zinke related the method of Parry in anointing the hand with oil and pushing the head far up; in many cases the head is then delivered by the action of the uterus on the head in its new position.

Dr. John M. Duff. Pittsburg, distinguished between delayed labor and tardy labor. He agreed with Dr. Davis in recommending the pelvimeter. This would make our young men safer practitioners.

Dr. W. H. Hoy, Battle Creek, Mich., related a case which he had delivered within the last twenty-four hours.

Dr. Mosher, in closing the discussion, said cocaine had been used by him in a hundred cases and he could not see that it did any good. The man who uses the forceps indiscriminately may think he does not rupture the peritoneum, but he does.

Dr. Davis, Philadelphia: One way of expediting labor is a free movement of the bowels by an injection of castor oil, spirits of turpentine and yolks of eggs. Antipyrine, not to exceed $2\frac{1}{2}$ grains per hour, will expedite labor. Greater doses will probably delay labor. In my mind there are only two indications for the use of forceps, viz: *those of Schroeder*, "positive danger to mother or child." No consideration of time would induce me to use them.

IMPAIRMENT OF THE VOICE, IN FEMALE SINGERS, DUE TO DISEASED SEXUAL ORGANS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, June 8, 1892.

BY C. HENRI LEONARD, A.M., M.D.,

PROFESSOR OF THE MEDICAL AND SURGICAL DISEASES OF WOMEN IN THE DETROIT COLLEGE OF MEDICINE, DETROIT, MICH.

This is a subject not treated of, or ever mentioned, in any of our text-books upon the diseases of women, so far as I am acquainted with them. Indeed, the only article I have seen upon the matter was one from Dr. Von Klein, of Dayton, Ohio, and appeared in a copy of THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION of last year. In this article the doctor makes these statements: "The most difficult cases the laryngologist has to treat are the diseases of the throat caused by the disturbance of the ovaries. It is a common thing to meet with cases of acute inflammation of the tonsils, larynx, pharynx and fauces, in females, during the menstrual periods. I have observed the voice of many professional singers, who have applied to me for treatment during the menstrual period, to be defective in gravity, force, and timbre, producing, in many cases, a husky sound as of a low masculine order. In many cases of ovarian disturbance, enlargement and hypertrophy of the tonsils and soft palate are observed, hence the laryn- an accomplish but little without the assist- competent gynecologist."

To better introduce my subject I will now read a letter from a quite noted soubrette who was under my care for some months for uterine trouble, and who had herself noticed a marked failure in her voice, but did not specially attribute it to uterine disease, until I particulurly called her attention to it as the probable reason for her voice failure. Her letter is dated "Dec. 5, 1889," and reads as follows:

"Dr. Leonard: I am now leaving here and have written in a hurry and do not know as I have given you the points you wished, but this one fact is conclusive and that is, the sexual organs not only *go with the voice*, but *control* it. I have been an actress and singer for a number of years, and as my special trouble grew upon me my voice lost purity of tone, and also lessened its range, till, from a high mezzo, I could do only a contralto range. Now that I am nearly recovered I sing with greater ease and have regained purity of tone, whilst in the upper register of voice *I have gained two full tones*, and am firmly convinced that I should have lost my singing voice entirely had I not have had the special treatment by you. My improvement has been so great that the singing professor, under whom I have been training, not knowing I was under special treatment, has taken to himself the full credit for my increased power and range of voice. Sincerely yours, etc."

Some two years after this, or during the past fall, the actress being in the city, she called upon me and reiterated what she had witten me in 1889, saying that she had permanently retained the two upper notes that she had gained during my treatment, and that there had been no relapse of the special troubles for which she had been treated by me. She also gave the history of a friend of hers, another professional singer, that had a similar experience to her own.

Now, while I do not think an increase of two notes in the vocal scale, from the treatment of a singer's sexual organs, is an occurrence to be expected in the majority of instances where a soprano may need a gynecologist's attention, still, I am satisfied that the popular notion that obtains with them—a huskiness of the voice at the time of the periods, is well founded; and I am sure my experience with several other cases would warrant me in asserting that the tone, pitch and range of voice of female singers is seriously encroached upon whenever they have *any* disease of gravity affecting their sexual organs.

It will be noted that Dr. Von Klein laid the greater stress upon the ovarian troubles: in the case of mine just reported, as well as in several other cases that have been under my care, the ovaries were not specially diseased; indeed, the ovarian symptoms were the least prominent, the main ones being uterine. In the case reported of the soubrette there was anteflexion and narrowing of the uterine canal, with severe endometritis. These trouble were treated and no attention paid to the ovaries, their recovery taking place without this. Of course, the two organs, uterus and ovary, are so intimately connected arterially and nervously, that a severe uterine inflammation may set up an irritation in the ovary; this I do not attempt to deny: but, curing the uterine trouble, the ovarian is cured as well. What I would specially wish to emphasize then, in contra-distinction to the claim set up in Dr. Von Klein's paper, is that to the uterus, more than to the ovary, we must look for the cause of imperfect voice in many of our female singers.

When we consider the intimate connection of the uterus with the great sympathetic nervous system, and the frequent deleterious impression of the stomach, heart and head reflexly therefrom by the way of this nervous connection, it is but carrying the same reflex process but one step farther when we assert its reflex influence over the organs of the voice. If good singers have themselves noticed this, at their regular monthly periods, and so have abstained as much as possible from the critical exercise of their voice at these regularly recurring periods, and many have so told me that they have noticed the prejudicial influence of these periods over their voices, then it stands to reason that an inflamed or conjested uterus will, at other times, also prejudiciously affect the organs of voice and song.

In tracing out the chain of nervous connections between the uterus and the larynx we find that, according to Bernard and Bischoff, if the spinal accessory nerve be cut or torn away, all the other cranial nerves remaining intact, there will be complete loss of voice. The same phenomena are observed if the inferior laryngeal be destroyed.

The motor fibres of the pneumogastric, so far as the formation of the voice is concerned, are derived from the spinal accessory: the pneumogastric is specially brought under control of the uterus from .its connection with the solar plexus that so freely supplies the heart and stomach. An inhibition of the spinal accessory could, physiologically, occur by a perverted nerve influence set up at the uterine or inferior hypogastric plexus; this influence would be transmitted directly to the solar plexus and reflexly therefrom to the spinal cord, heart and stomach, and then through the pneumogastric to the spinal accessory, recurrent laryngeal and glosso-pharyngeal, thus paralyzing, in a measure, the motor influence of all these nerves over the muscles of phonation.

The muscles governing pitch of voice are the crico-thyroid and the thyro-arytenoid—the muscles of tension of the vocal cords. These cords vibrate from 572 times (the gravest note) to 1, 606 times (the highest note) each second of time, in our soprano singers. You can readily see, then, that the slightest impairment of the normal innervation must necessarily render organs so extremely delicate as these cords are deficient in their higher tensions and consequently imperfect in their range and action; huskiness, from the less tension of the vocal cords, would be one of the first symptoms of deficient nerve influence, a loss of a tone or so the natural result of a greater impairment of its nervous tonicity.

When you now combine these immensely frequent vibrations of the vocal cords, in the female, with the other muscle combinations taking place in the phenomena that we term phonation, remembering that there are something over one billion of these combinations with the other laryngeal muscles (for Bishop avers that for every modulation of the human voice there are, at least, 100 muscles that must be brought into perfect coördination), we have the grand total of 20,000,000,000,000 of muscular combinations in phonation; when this is properly considered, I say, the only wonder is then, not at an occasional lapse of coördination or the loss of a tone, but that even in the most perfect health and training such exactness of the scale as seen in the vocal accomplishments of our singers can ever be obtained.

That there is this intimate connection between the nerves of the uterus and those of the larynx, as above claimed, I am positive of, for I have time and again witnessed their reflex action on several of my patients. One of the most distressing exhibitions of laryngeal spasm I ever saw was in the person of Mrs. S., 40 years of age, and suffering from a large uterine fibroid. She had this reflex laryngeal spasm to that extent that suffocation was imminent at each application of anything to the endometrium. I, as well as the patient, dreaded each bi-weekly visit, as she would strangle until she became black in the face, and lose consciousness, at times, at each application; any point of the uterine canal seemed equally sensitive whether probe, sound or medicament was used. As the uterine irritation was progressing towards cure she had these spasms less violently; but the immediate and direct connection of the uterine nerves with those of the larynx was conclusively shown, dozens of times, to the students that were with me at my clinics whenever this patient would call.

I have under treatment, at the present time. a private patient that manifests these laryngeal spasms at each intra-uterine application, though to a much less degree of severity than the case just detailed. Still another private patient, though having no spasm, has a marked laryngeal pain at each application, and during the times of treatment complains of great pain in the larynx; indeed, the most of her pain is referred to this organ rather than to the uterus, though there is no laryngeal difficulty, but a marked endometritis. These cases of laryngeal spasm and pain were and are not the minor laryngeal difficulty known as "globus hystericus," a disease affecting reflexly the vocal organs and throat and which was well-known in the time of Hippocrates.

A further case of prejudicious influence over the voice from the reflex action of the pelvic organs, though seen in the male, is detailed by Dr. Sivers, of Ft. Wayne, Ind., in a recent number of the *Medical Age*. The doctor's case was one of chronic laryngitis where the patient could not speak above a whisper for two years and where the exciting cause of the trouble was found to be pile tumors in the rectum; proper treatment being addressed to them the difficulty of voice was permanently relieved. The nerve fibres in the male pelvis are analogous and similar to those in the female, hence the results obtained in Dr. Siver's case but confirm the position taken in the claims I have made of the influence of the pelvic organs over the voice; a further analogue is seen in the modification of the voice in soprano male singers who have been submitted to castration.

PERITONEAL IRRIGATION AND DRAINAGE.

Read in the Obstetrical Section at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich , June 7, 1892.

BY A. H. CORDIER, M.D.,

OF KANSAS CITY, MO.

If an apology for presenting a paper before this great body of learned men, is necessary, my excuse is, the diversity of opinion among surgeons, and in some instances ignorance, of when and how to use intraperitoneal irrigation and drainage. You will find one. surgeon using neither, another resorts to drainage alone in some of the many ways of using, another uses both according to his ideas, which of course he is entitled to follow, provided he gets the good results from his method of using these agents that are obtained by other surgeons perhaps by a different method.

The latest works on abdominal and pelvic surgery contain, like the older books, very short and misleading articles on the indications for peritoneal irrigation and drainage, and still less explicit are the directions how to use these agents for good intelligently and correctly. This diversity of opinion among revolving book rack authors leaves the inexperienced beginner in a position of perplexity and doubt as to the special course he is to pursue in his early work. No one should undertake to irrigate or drain a peritoneal cavity before he has witnessed and assisted a master of this special branch in our healing art in a large series of cases, and has mastered his teacher's technique.

If you hear an operator condemning drainage, and on examining his mortality column, find a death rate of 8 to 12 per cent. in a series of cases and a number in this list under heading of "cause of death unknown," "peritonitis," "heart failure," "hæmorrhage," you may rest assured that some deaths could have been averted by the irrigator and tube. "People seldom improve when they have no model but themselves to copy after." To illustrate this diversity of opinion among gynecological and surgical writers, I will with your kind indulgence, quote from a few of the standard textbooks. One author condemns drainage and on same page tells how he uses it: "A rubber tube perforated for three inches of its abdominal end and long enough to run out over the edge of the bed into a basin filled with carbolized water to prevent the entrance of germs." The same writer speaks of secondary drainage to remove putrid discharges collected in the pelvis to prevent septic symptoms, and adds: "Of course no one would think of performing this operation until septic fever is evident."

Another writer says: "If a drainage tube has been used it should be well *corked* (italics mine) until symptoms of blood poisoning arise when it is to be opened frequently to admit of the escape of any fluid that may be in the cavity * * * and a hard rubber syringe passed to the bottom of the tube to remove what has not run out."

A noted German operator and author writes: "After a vaginal and supra-vaginal hysterectomy, I continue to use drainage of the pouch of Douglas after this operation in spite of various publications which state that the omission of this is not injurious. I attribute my success essentially to this treatment in connection with two observations which I have made. One case perished from septic peritonitis in which the tube was allowed to escape and a collection of secretions formed at the bottom of Douglas pouch. The second case I was induced by the publication of successful cases without drainage to omit the latter which I otherwise employed. The patient recovered well from the shock of the operation; in the course of the second day, however, an extremely threatening collapse occurred with pallor of countenance and increased frequency of pulse. The symptoms disappeared at once as I had the patient sit up, and separated the sides of the opening in the vault of the vagina by passing my fingers into it; a large amount of sticky and foul fluid was discharged. From this moment the patient got better." He says on the indication when to remove the drainage tube: "usually between the third and fourth day a peculiar period of drawing is experienced in the umbilical region; I then remove the tube. Since I have employed this method of treatment the results of supra- computation have become essentially better ’ This great operator lets this lesson from nature in drainage teach him nothing. In 77 salpingectomies this same operator had 14 deaths, with no history of drainage. Of this number 10 died of sepsis or the result may be traced to this source as a cause.

One aspirant to operative fame, when discussing drainage with a professional brother, said: "I do not see how you can drain the pelvis with the tube standing straight up." His wise senior replied: "Turn the patient on her side and let it run out."

I have seen a drainage tube pushed down into the pelvis and the dressings and bandage applied over its outer extremity, and that too by a teacher before his class, at same time remarking that he had had a number of fecal fistulæ following the use of the tube and that it was very troublesome to keep the dressings clean and dry.

Hydrostatic pressure on the diaphragm has been advanced as a counter-indication to the use of the irrigator. An outward flow during your irrigation is obtained if used properly; you rarely wash the diaphragm unless you have been using the Trendelenburg position and had your patient's diaphragm and liver flushed with pus or other septic fluids during the operation. You do not use water hot enough to paralyze the solar plexus as some apprehend.

The general surgeon long since called attention to the fact that old abscesses with a limiting wall if disturbed, in many cases lead to systemic infection by changing the character of this breastwork to one with absorbing functions. While this fact was long since recognized, it was not suspected that the changes wrought in the surrounding tissues by surgical interference lead to a secondary infection by the admission of new agents into the abscess cavity, yet every effort was made to keep an outward flow of the discharges by drainage, through counter openings, vapor baths, cathartics, diuretics, etc., etc., all drainage agents.

If we accept or reject the germ theory of the suppurative process and its prevention by *antiseptic* or *aseptic* methods the truth remains unaffected that it has been through this channel of purification that we have learned that cleanliness in surgery is next to godliness. If germicides are or are not used while operating the deluent acts as an absolvent to the dirt or as a destructive agent to the pathogenic bacteria, and the same end is obtained provided both methods are carried out with equal care and diligence, although possibly by a different process. One by washing away the dirt or germs present, the other by destroying or inhibiting those not destroyed.

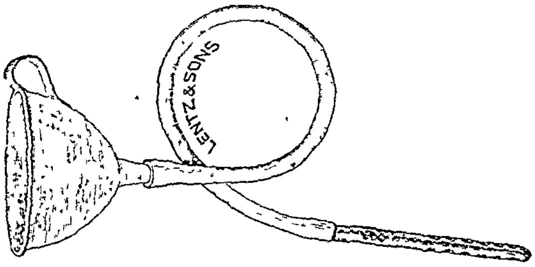
The object in either method is to reduce to a minimum the amount of chemical substances or number of germs so that the functions of absorption, destruction, and elimination are not overtaxed, at the same time reducing to the lowest ebb the fermentative fever tendency, by removing at the time of the operation as much of the fever producing agent as possible by irrigation and keeping the locality clean by thorough drainage afterwards. There are localities in the body where germicides cannot be used in strengths sufficient to have the action desired without producing toxic effects. Fortunately, it is in this same locality that we have the greatest absorptive and eliminative function developed.

In peritoneal surgery irrigation and drainage are positively indicated and indispensable in the majority of cases. The same principles hold good in draining the peritoneal cavity that are applicable to other arts of the body. No surgeon, with all the antisep-c precautions possible to be used in opening a dif- sed abscess of the thigh or other parts of the body would think of such a thing as at once closing the wound hermetically, leaving many broken down shreds of diseased tissue dangling in the abscess cavity. He may have irrigated the cavity thoroughly with a "1 to 1,000," yet he would not feel it safe to close the wound until after he had made counter openings and introduced drainage tubes. This being as near ideal surgery as it is possible to obtain in these cases. The presence of the tube does not have special healing virtues only in as far as they keep the parts free from the poisonous discharges, permit the structures to come in contact and heal in their normal relations and at the same time by this system of drainage avoid the absorption of septic and putrid material.

It is a fact long since recognized that aseptic blood *clots may become organized*, if not absorbed, and give rise to firm and dense adhesions. If any pus forming agents are introduced during the operation, or even those already present in limited numbers, the presence of much blood in the peritoneal cavity prevents to some extent the absorption of these pathogenic bacteria and their destruction by the phagocytes, and thus being allowed [illegible]emain, rapidly multiply in this fertilized hot-bed, p[illegible]yzing this function of the white cells by the overwhelming numbers, attacks the peritoneum, producing a rapidly fatal peritonitis in the majority of instances. If this truth is accepted no conscientious surgeon should fail to irrigate and drain after operations for the removal of pus tubes, dermoids, etc., etc., or where there was much effused blood during or following an intra-peritoneal operation. A peritoneum cannot absorb liquids as long as it is, so to speak, "water-logged" or œdematous. Any method or treatment, whether by drainage or by hydragogues have the same object in view, that is the removal of the effused liquid or its elimination by hastening its absorption. In "hulling" out adherent pus tubes, dermoids, breaking up adhesions, many surfaces are of necessity left denuded of peritoneum. These surfaces have very poor absorptive powers, yet they pour out much fluid which, if not removed early, is liable to become putrid or septic. It is a well recognized fact that a traumatism produced by aseptic agents leading to plastic inflammation is localized to the seat of the injury and does not spread much beyond this location as long as the surroundings are kept aseptic. Also that the germ producing powers of a once begun septic peritonitis are unlimited and the bacterial hot bed being located within the cavity affected, accounts for its wide spread. With this truth before us we should in every case do all operations, if not antiseptically, aseptically, and to insure the maintenance of this clean condition, endeavor to keep the cavity as clean as possible after the operation by not only draining the non-decomposed secretions and thus reducing the severity of the aseptic fever to the lowest ebb, but at the same time reducing to a minimum the number of pathogenic germs accidentally or unavoidably introduced during the performance of the operation, and thereby thwart an attack of acute peritonitis. In cases operated on where there existed at the time of the operation a free dropsical fluid, a drainage tube must be introduced, as the peritoneum cannot absorb anything when in this condition, and by keeping it dry a few days the effusion in many cases ceases to re-accumulate unless the presence of the fluid be due to malignant disease of the peritoneum or other abdominal or pelvic viscera. *In old and debilitated patients* the absorptive powers of the peritoneum are lessened and in these cases we find an indication for drainage. *Operations involving structures in a state of inflammation* are always followed by a profuse flow of serum, which is more liable to become purulent or septic than if performed in healthy structures. You have less pain in the cases that are drained as the pain from pressure on the nerves caused by the effused liquid is removed with the liquid. Fluid is liable to undergo decomposition from contamination through the intestinal walls. The accumulation of fluid in the pelvis must be prevented, if possible, after all operations.

The above language as a short plea for drainage is equally as applicable to the use of hot water irrigations in abdominal and pelvic surgery, for where drainage is indicated irrigation is demanded. Many surgeons decry the use of the tube by stating that they do not see any cases in which it is needed.

Irrigation.—Freshly boiled, distilled water cooled to 102° F. to 110° F., should be used in irrigating. After the performance of the operation and before the stitches have been introduced, the cavity should be thoroughly washed by means of the irrigator.

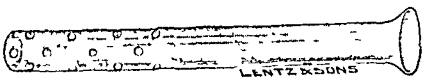


The irrigator consists of a rubber tube three feet long and three quarters of an inch in diameter, to one end of which is attached a funnel, to the other a hard rubber nozzle about ten inches long with side perforations, the distal end being closed except a small opening in the center. The patient is turned on her side toward the operator, who with two fingers of the left hand introduced near the lower angle of abdominal incision and slightly separated, the nozzle of the irrigator is introduced (having first started the water to running) into the inferior angle, is guided by the fingers to the lowest recess of the pelvis and moved about from one locality to another while the water is being poured into the funnel from a pitcher held in readiness, to be used for this purpose only.

Just before beginning the irrigation the anæsthetic should be pushed to profound anæsthesia; if this precaution is not observed, the patient will resist your efforts and cause the intestines to protrude through the incision and cause unnecessary delay in replacing them and keeping them replaced. This is an illustration of the stimulating and reviving effect of the hot water. While thus using the water it is surprising to see with what rapidity and force the large blood clots and other foreign bodies prese[illegible] ar[illegible] forced from the cavity. During the flow of [illegible] the operator should gently move the vi[illegible] and mis- that the fluid may come in contact with [illegible]eritoneal and corner. As long as the water comes stained, especially after using considerable hot water you may know that some hæmorrhage is going on, except in extra-uterine pregnancy with rupture or where you find much free blood and soft clots; here the water will continue to return blood stained as long as you use it and will lead the inexperienced operator to think that an alarming hæmorrhage is going on and cause him to seek the source of the bleeding. The blood stained fluid returning through the incision is much darker in this condition than if a hæmorrhage is actually going on during your irrigation. The operator should always test the temperature of the water by introducing his hand into each pitcherful as it is being raised to the height of the funnel, which is held by his assistant. The irrigator should always be started running before introducing the nozzle. In some cases it will be necessary to use much more water than in others, as in cases of ectopic gestation with rupture in which a large quantity of blood is found, or in ruptured pus tubes or profuse hæmorrhage from broken down adhesions, etc., etc. Its hæmostatic effects are often quickly noticed, much to the satisfaction of the operator, where there is an alarming hæmorrhage from torn vessels or a general oozing. Its beneficial effects are also perceptible in many cases in preventing shock or causing the patient to rally from this condition, if it exist. If your operative technique has been good and your surgery not too "chronic," your irrigation satisfactory and your drainage tube *properly introduced* you may expect recovery in a larger per cent. of these cases than you could expect without these agents.

In addition to the cases mentioned irrigation should be used in all cases of intestinal and bladder injuries where there is a perforation and extravasation, also in appendicitis, surgical operations on the gall-bladder and kidneys where there is an escape of bile, urine or pus. In using the irrigator avoid too rough handling of the nozzle lest you disturbed your pedicle ligatures and start up an alarming hæmorrhage. After thoroughly flushing the cavity the residual fluid is removed by soft clean sponges. A small quantity of the clear fluid left can do no harm, in fact in some cases, as in ruptured tubal pregnancy, it is absolutely impossible to leave the peritoneal cavity free from clots and fluid. In this condition water is left on purpose that it may aid in liquefying the soft clots entangled in the folds of the omentum and mesentery, that the liquefied product may be removed by aspiration through the drainage tube and the work of digestion and absorption by the peritoneum lessened and hastened. Having completed your irrigation and introduced your *silk worm gut* sutures, before tying them you introduce the drainage tube, which should be used with rare exceptions, where in your opinion it has been necessary to use irrigation. Some operators introduce an extra stitch at the site of the tube and do not tie it until the tube is removed; this I think unnecessary.

To Dr. Joseph Price we are indebted more than to any one American or European surgeon, for the intelligent and correct way of using these agents.



[illegible] is a straight glass one of lengths and individual cases, as one tube cannot be adjusted to accurately fit all cases. The lengths varying from three inches, for children, to nine inches to meet the requirements in very fat subjects with greatly thickened abdominal walls and a pelvis of great depth. The average length however is about six inches. I have not seen a *good* tube whose diameter was over five-eighths of an inch or less than one quarter. The tubes are straight, the end introduced has an open mouth, that large pieces of detached shreds of adhesions or blood clots may be removed by aspiration; many small round perforations mark the sides of the tube for the first inch and a half. The distal end is flanged (not down on the side an inch as I have seen in many tubes) the same as you see in the commonest tube. This projection retains the sheet of rubber dam, at the same time prevents the tube escaping into the abdominal cavity, not a very likely accident if the tube is a properly selected one and introduced in the right way. Having selected your tube, which by the way must be done before hand, that it may have been properly prepared before you are ready to use it, you introduce it precisely as was directed for the introduction of the nozzle of the irrigator into the pelvis or the region to be drained. While your assistant steadies the tube and thus retains it where you intend it should remain, you tie your sutures and accurately adjust the divided structures making the tissues closely fit the circumference of the tube. After removing the fluid collected in the tube at this time by means of a long nozzled piston syringe and satisfying yourself that everything is all right you take a piece of rubber dam fifteen inches square with a small niche in its center, by stretching this little opening you are enabled to slip it over the flange of the tube and being released contracts so accurately fitting the tube as to make it impervious, and thus avoid soiling the dressing by the escaping drainage, should it, by carelessness or from inattention on the part of the nurse, be permitted to overflow. Again removing any fluid collected, you cover the opening in the tube with absorbent cotton and neatly folding the four corners of the rubber dam over this, entrust it to the care of your assistant while the many tailed abdominal binder is being adjusted.

One corner of the folded dam is secured to the binder with a safety pin and after emptying the tube again your patient is put to bed surrounded by the usual precautions. Of course gauze is placed over the wound, around the tube, by splitting each layer and over this the binder is placed.

The nurse is instructed when and how to cleanse the tube. By this arrangement of the dressings the tube can be pumped out as often as it fills without in the least disturbing the patient by the removal of the dressings.

Every aseptic precaution should be observed in the emptying of the tube. The hands of the nurse or the physician should be clean, the syringe should be scalded each time before introducing it, the mouth of the tube must be cleansed by a pledget of absorbent cotton before the syringe is used. While cleansing the tube with the syringe if the piston fails to slip easily you may know that a blood clot or shred of some adhesions have become engaged and by withdrawing the nozzle you may, and often will suced in removing the foreign body. After drying the be a fresh supply of absorbent cotton is placed ver its mouth and the corners of the rubber dam eatly folded over it and pinned. This same precaution should be observed at each cleansing of the tube. The tube should be rotated and raised a quarter of an inch two or three times for the first twenty-four hours. This relieves pressure on the intestines, if any exist and at same time prevents the omentum becoming entangled in the holes of the tube, an accident more of an anticipated dread than of actual occurrence. After removing the glass tube if there is any fluid likely to collect within the next twenty-four hours, a small rubber tube may be left in the site of the glass tube by introducing it through the glass tube before it is removed. This in turn can usually be removed on the following day.

By using drainage as I have described, the bandages and dressings are kept dry and clean, do not have to be disturbed until the time arrives to remove the tube or stitches. When the tube fails to show much over a drachm of fluid, collected in an hour or two, the [illegible]e has arrived to remove it, unless this small a[illegible]nt of fluid is purulent or offensive. Ordinarily the tube can be removed with safety on the second or third day. The opening soon closes and there is no more danger of a ventral hernia following than if drainage had not been used.

Drs. Price and Wylie years ago called attention to the fact that many deaths from so-called shock were in reality deaths from concealed fatal hæmorrhages and advocated the introduction of the tube in these cases in which there was free oozing during or following an operation. The presence of the tube, by keeping the peritoneal cavity free from lymph is a direct and most efficient hæmostatic. This fluid normally present in small amount is greatly augmented by the manipulation of the peritoneum during the performance of an abdominal section, and like the moist fomentations over the scarrified surface of any other part of the body, promotes bleeding and prevents the formation of firm clots in the mouths of the small blood vessels torn across while breaking down adhesions.

Gentlemen, if you will use "Peritoneal Irrigation and Drainage" as I have described it, you will not, I am sure, condemn the method. They will help reduce your mortality, I am sure.

1016 East 9th Street.

DRAINAGE IN ABDOMINAL SURGERY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY DONNEL HUGHES, M.D.,
OF PHILADELPHIA, PA.

Drainage of the peritoneal cavity is one of the most important subjects connected with abdominal surgery, and yet at the same time, it is one of the most disputed points. The difference of opinion that exists to so marked a degree is due, no doubt, to the fear that the tube may act as a source of septic infection, or by its use the abdominal walls are weakened to such an extent as to favor the development of ntral hernia or the formation of a fistulous tract.

accepted fact, that the object of drainage is ove all those deleterious substances which, if ed to remain within the peritoneal cavity or any other cavity within the body, would in a greater or lesser degree retard the progress of the case toward recovery, and in many instances endanger, if not sacrifice the life of the patient. I do not believe that it is necessary, or even advisable, to use drainage in every case of abdominal section. If aseptic conditions are scrupulously maintained throughout the operation, and all bleeding vessels secured, the abdominal cavity thoroughly irrigated with pure distilled water (that is warmed and has previously been thoroughly boiled), whenever any blood or foreign substance has escaped into it—under these circumstances drainage is not necessary; and if not necessary, it is certainly not advisable. It should not be lost sight of for one moment that the drainage tube is at best, a foreign body, and capable of causing a good deal of irritation, and in many cases, if great care is not exercised, it is a fruitful source for the entrance of septic matter. Cases very frequently present themselves in which it is absolutely demanded for the safety of the patient. The cases in which it should be used are very numerous. I will mention the cases in which its use is necessary: 1. When pus or any other septic material has entered the peritoneal cavity before or during the operation. 2. When extensive adhesions have been severed, and there is an oozing surface. 3. When hæmorrhage is feared, or when present and cannot be controlled. 4. Where there is malignant disease and danger of subsequent infection. 5. In cases where simple or tubercular peritonitis exists, or where there is a large accumulation of ascitic fluid. When it is deemed advisable to use drainage, the question then arises, what device should be employed for that purpose? It should be answered in the following way: If there is hæmorrhage that cannot be controlled by the application of ligatures or hæmostatic forceps, or by some of the many methods that we have at our command, the best plan is to pack the bleeding cavity with a strip of iodoform gauze and bring the end of it out at the lower angle of the wound. We then have tampon and drainage combined. At the expiration of forty-eight hours the gauze should be removed. If the bleeding has ceased and there is need for drainage, a small rubber or glass tube may be substituted for the gauze; if there is still a tendency to hæmorrhage, the gauze may be reintroduced and allowed to remain a few days longer. In cases where there is oozing that has been caused by the breaking of adhesions, or when pus has escaped into the peritoneal cavity, or when the large bowel has been ruptured, and the rent cannot be found, a glass tube open a both ends, and perforated on its sides with small round holes, should be used. The tube should be long enough to reach from the lower angle of the wound to the bottom of Douglas' pouch. The circumference of the tube should be determined by the quantity and consistency of the material that it is expected to convey out of the cavity; the smallest tube should be selected that will properly carry the fluid. Care should be taken when the tube is introduced that it does not press upon a loop of intestine instead of upon the floor of the pelvis. Before inserting the tube a suture should be introduced and left unfastened, its object being to close the opening that remains after the removal of the drainage tube, otherwise a weak cicatrix might remain, that would favor the formation of ventral hernia. After the tube is in its proper position, and the abdominal wound closed and the usual antiseptic dressings applied, a piece of rubber sheeting about one foot square, with a small hole in the centre of it, should be sprung over the tube in order to prevent the discharge soiling the dressings and infecting the wound. Aseptic absorbent cotton should then be placed over the opening in the tube to absorb the overflow, and over this the rubber sheeting is folded and retained in position with a safety pin. The most important point to be observed in the use of the drainage tube is frequent and thorough cleansing. No regular or fixed time can be set for emptying the tube, but a good rule should be to clean it whenever it is filled with fluid, no matter how short the interval. The fluid is best removed with a long nozzle uterine syringe, or a piece of rubber tubing attached to an ordinary syringe. When hæmorrhage is indicated by the flow of pure blood from the tube, the blood must be constantly removed, as by keeping the bleeding surface dry coagulation is promoted, and the hæmorrhage very often arrested. After the drainage tube has been in use for forty-eight hours, it becomes surrounded by the tissues, which are retained in that position by adhesive inflammation, therefore after that time, it is of very little if any use in draining the abdominal cavity. It will, however, drain the pelvis for a much longer time. The tube should be raised two or three inches out of the wound every day and turned completely around on its axis, and allowed to drop by its own weight, in order to prevent prolonged pressure on any one point, and also to prevent the organizing exudation from penetrating the lateral openings in the tube. The drainage tube should be allowed to remain until the discharge is reduced to 2 or 3 drachms of clear serum a day, this usually occurs within three days. After it has been removed, the free ends of the suture that was left for the closure of the drainage tube wound should be tied.

NON-MALIGNANT, NON-TUBERCULAR, NON-HYDATID CYSTIC DISEASE OF THE PERITONEUM.

Read by invitation in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY JAMES F. W. ROSS, M.D.,
OF TORONTO, ONT.

The subject selected is not likely to prove of interest to the general practitioner; it is not likely to open up any practical discussion, but it is of interest to the abdominal surgeon. The disease to be discussed is allied with acute peritonitis on the one hand and intermittent pelvic peritonitis on the other. The disease is cystic and yet inflammatory. It is therefore essential that we should consider the pathology of cysts and the pathology of peritonitis. Authors vary in their classification of cysts, and yet agree in the main distinctive features of these interesting aberrations from a normal condition. For our present purpose we need but remember that we have epithelial cysts and endothelial cysts. Epithelial cysts are cysts of retention. Endothelial cysts are formed of the dilatation of cavities in connective tissue such as bursæ, tendon sheaths and obstructed lymph channels (Zeigler). An inflamed bursa, from the inability of the serous lining to absorb the fluid poured into its interior, becomes a cyst, and if we would carry the analogy to what might be considered too great a length, the inflamed peritoneum, from the inability of its serous lining to absorb the fluid poured into it, becomes a cyst. Newly formed or false membrane may surround fluid so that portions of the fluid become collected in sacs, and thus inflammatory cysts are formed. Pus is surrounded in this way in the abdomen, and pockets of encysted pus are shut off from the general peritoneum. The very same formation of pockets of encysted serum takes place subsequent to a peritonitis.

We have other cysts, such as the cysts of disintegration, and the cysts formed around foreign bodies, such as hydatids and blood cysts, but with these we have nothing to do at present. But I wish to mention the cysts that are found filled with lymph instead of serum, from the obstruction of the lymph channels; with blood instead of serum, from the intracystic rupture of one of the newly formed and delicate vessels; with air instead of serum, a condition that has been noticed by several good observers. The latter condition is a pathological curiosity. One case in which this condition was found has been well recorded in the London Pathological Society's Transactions, Vol. xxii. The patient suffered from a duodenal ulcer, and the supposition was that flatus escaped beneath the peritoneum and produced the condition. The cysts were like the cystic dilatations so frequently found hanging from the fimbriated extremity of a *normal* Fallopian tube, or from the tubules of Kobelt in a *normal* broad ligament. Some were as large as a hazel nut. They hung by a single pedicle. Some similar ones contained coagulated blood instead of air, but even in these, hollow spaces were found on section. The parietal as well as the visceral peritoneum was affected. In his discourse on the case I find the following, written by the author of the paper: "Were the cysts which contained the air of independent formation, or were they produced in any way by the emphysematous bubbles? Against the first view it must be urged that cysts of the peritoneum are hardly known; nothing of the kind is mentioned in the standard text-books." In the latter sentence you have my excuse for presenting to you such a subject. That I should thus early in my lifetime have met with two cases would seem to indicate that the disease is not of such rare occurrence. My friend, Dr. C. A. L. Reed, has promised to put two cases on record and to give his views regarding the etiology and treatment of the disease. We will return to the pathology after detailing the cases. My own cases were as follows:

Case 1.—Mrs. A. L. æt. 22, had evidently suffered from gonorrhœa two and a half years before she came under my observation. The history was that of intermittent pelvic peritonitis. When maki[illegible]mination, I felt what I concluded was a [illegible]. and asked her physician, Dr. Dawson, why she kept her bladder so full when she knew we required bladder and rectum empty. She was at the time under the influence of an anæsthetic, so that I passed a catheter myself.. No water came, and yet I felt sure that the fluid must be in the bladder. The wall surrounding the fluid was lax and not tense like the wall of an ovarian cyst. I then felt two pus tubes, one on each side of the uterus, and advised their removal. The collection of fluid was a mystery I was unable to solve.

On opening the abdomen three days after (namely, on November 4, 1891), I found peritoneal cysts looking like white grapes. Owing to the matting of bowel and omentum to some mass, I put the patient in Trendelenberg's position to facilitate the exploration. After pulling up the omentum a dark-colored cyst was found, occupying the position usually occupied by the bladder in front of the uterus. It had a grayish, semi-gangrenous appearance, and yet when tapped, the serum that was removed was clear, limpid and transparent, and of light amber color. The dark appearance was evidently due to the venous blood filling delicate newly formed vessels. About 4 ozs. of fluid were withdrawn. The sac then bled very profusely upon attempting to enucleate it. It was in the way, and was removed by ligature in sections. The pus tubes were then peeled out and tied off. The severe manipulations had ruptured several of the small pendulous cysts, and they bled freely. It was therefore necessary to tie off about twenty-five of these little bodies. Each was filled with the same kind of fluid, and each hung by a slender pedicle. They resembled the little pendulous cysts accompanying and supposed to be indicative of malignant disease. May not these little bodies, when accompanying malignant disease, be simply due to the prolonged and gradual peritoneal irritation?

The patient made an excellent recovery. I fear that she would have lost her life from hæmorrhage had I not used Trendelenberg's position, because it was difficult to find and tie all the bleeding points. The patient has since developed secondary syphilis, but I presume that it has been contracted since operation.

Case 2.—Mrs. H., æt. 33. First seen October, 1889, when I diagnosed uterine fibroid, and advised removal of ovaries and tubes. Patient went into the hospital intending to have the operation done, when she developed an abscess in the left groin. I opened this and found that it led down to the left side of the cervix uteri. She then convalesced, and left the hospital without having any further operation. The pain continued and the sinus remained unclosed. I saw her again in January, 1892, and advised further operation to discover the exact nature of her trouble. I operated on February 12, 1892. On opening the abdomen, I found a fluid tumor, evidently between the bladder and uterus, very adherent to bowel and desperately fixed in the pelvis. Patient placed in Trendelenberg's position, and the adhesions between the cyst and rectum and uterus torn through. I had difficulty in avoiding the ureter on the left side. At last I was able to make out the left uterine cornua. The left tube was coiled up and somewhat thickened, and very hard. The tumor I suppose was one of the left ovary, but so adherent that no definite pedicle could be made out. I tied it off both at uterine and rectal end. Hæmorrhage from the bowel was controlled in several places by ligature. The peritoneum was studded in several places with small grape-like cysts exactly similar to those mentioned in Case 1. I tied off about six or eight of them. The right ovary and tube were not enlarged, though imbedded in adhesions. The patient made an excellent recovery and is in splendid health.

Such cysts as those described are not, so far as I know, found in any other serous cavity. Why should they affect the peritoneum alone? I believe the answer to this question will give us a clue to their true pathology.

I recognize two forms of peritonitis, acute and chronic. The acute may become chronic, and if the formation of adhesions be considered as a chronic condition, then acute peritonitis may be said to always become chronic.

Acute peritonitis may terminate in the absorption of the fluid or in the non-absorption of the fluid poured out.

It may terminate in the formation of adhesions or of false membranes. It may be purulent from the first or become purulent, and the pus may be pocketed in multiple pockets or the serum may remain unabsorbed, and become pocketed as it did in Case 1, and terminate in the formation of numerous pendulous cysts.

Now to return to the pathology of cysts. Are these cysts simply the representatives of isolated pockets, or are they formed in some other manner? My own belief is that that they are simply the remnants of pieces of false membrane enclosing serum.

Cysts filled with air we have already considered. There are three other forms, excluding dermoids and hydatids, namely: those filled with serum, lymph and blood.

The lymph-filled sacs are probably formed by the formation of false membrane over the stomata and the escape of lymph beneath it. But believing as we do, that the lymph stream is away from and not towards the peritoneal cavity, it would appear as if this theory of lymph-filled cyst formation were incorrect.

How are the blood cysts formed? Is the cyst originally a serous cyst with secondary hæmorrhage into its cavity, or is it originally an extravasation that becomes a cyst? I believe the former, because subperitoneal hæmorrhages are usually found as flat spots of ecchymosis.

In the two cases recorded, the cyst wall was like the very finest tissue paper. It did not look like peritoneum, and I do not believe that it was peritoneum. From the peculiar foldings and bands running from surrounding parts to the cyst, I concluded that the wall was composed of false membrane. If composed of false membrane, then the cysts must be inflammatory in origin, and we had sufficient evidence of old inflammation to lead us to believe that this might be the case. And now in conclusion, let me say that I believe that we have a distinctly inflammatory cystic disease affecting the peritoneal cavity; that it is not of rare occurrence; that if the condition producing the inflammation be removed and the cysts tied off, the patient will become entirely well; that I know nothing of the ultimate result of such a case if left alone; and that I hope others will record any cases of the kind with which they have met.

Two practical points might be dwelt upon. First, that the rupture of such little vesicles might be a source of hæmorrhage into the peritoneum after operation: and secondly, that to avoid the danger of hæmorrhage, they should be ligated with fine silk when met with during the course of operation.

A REPORT OF EXPERIMENTS GERMANE TO THE SUBJECT OF ABDOMINAL SUPPORTERS AFTER LAPAROTOMY.

Read before the Section of Gynecology, at the Forty-third Annual Meeting of the American Medical Association, held in Detroit, Mich., June 10, 1892.

BY ROBERT T. MORRIS, M.D.,
OF NEW YORK.

Rabbits were used for the experiments because it did not happen to be convenient for me to use larger animals, although the latter would have been better. An incision about an inch and a half in length was made in the middle abdominal line in a series of adult rabbits and then the wounds were closed with catgut in two tiers. The first tier included peritoneum, muscle and fibrous tissues. The second tier united skin margins.

The method of examining the character of repaired tissues afterwards consisted in dividing up the abdominal walls into half inch wide strips, cut transversely, the rabbits having been killed with chloroform. The strips were then dissected in such a way that skin was separated from muscles and muscles from peritoneum. The strips of separate tissues were tossed into a beaker of water to prevent drying while tests were being made to determine the strength of any one tissue. The apparatus for the testing consisted of a pair of screw clamps and a spring balance registering pounds up to fifty. One end of a strip of tissue was fastened between two little blocks of wood with one screw clamp. Then the other end of the strip was gripped in the same way with the other clamp. The spring balance was hooked to one clamp. Then I pulled on the other clamp and watched the indicator of the balance until the tissues gave way.

The first rabbit was killed at the end of the third day. The strips of skin from an unwounded part of the abdomen pulled apart at a pull of about eighteen pounds. A corresponding strip of wall, including muscles and fascia resisted a pull up to about sixteen pounds. The peritoneum pulled apart at about seven pounds tension force.

Tissues of strips taken from a sutured segment, after the sutures were removed did not hold as far as the one pound pull point in this first rabbit.

At the end of seven days, the second rabbit was killed, and I wasted all of the strips in trying to get the delicate peritoneum separated fairly for tests. A third rabbit was then killed immediately and I learned that by a little trick of pinching up peritoneum in a certain way it could be dissected away from muscular walls. A strip of normal peritoneum and a strip of peritoneum including the wound line, each gave way at almost precisely the same tension point with eight pounds pull. A strip of normal muscular wall gave way at fourteen pounds pull, and a strip including wound line, gave way at the wound line with five pounds pull. A strip of normal skin pulled apart at about seventeen pounds tension, and a strip of wound skin gave way at two pounds pull.

At the end of ten days the fourth rabbit was killed. It was quite evident that the peritoneum at the wound line was similar to normal peritoneum in every way. At this time the muscular walls began to give way at the point of some stitch hole in the wound line, and although the separation was principally in the wound line, the tear began to extend into the normal tissues in the vicinity when the tension force was exerted. The skin still tore through the wound line without involving any normal skin in the tear.

At the end of fourteen days the fifth rabbit was killed. Wound peritoneum similar to normal peritoneum. Muscular tissues at the wound line did not tear open along any one direction, but when the strips were subjected to tension the fibres of the strip began to slide from each other very much as the threads of some woven material might slide apart. This process took place in strips from the wound line at practically the same pulling force that was required for separating the tissues of normal strips which gave way in a practically similar manner. In this fourteen day rabbit the skin still gave way in the wound line at a lesser pull than was required for the normal skin, but the sliding of fibres was observed to begin to extend into normal skin on either side of the wound at this date.

At the end of eighteen days the sixth rabbit was killed and all structures were found to be united by reparative processes as strongly as they ever would be apparently. It was observed, however, that tears which began near the wound line always ran to a stitch depression, or else they began at a stitch depression and extended out into the surrounding tissues.

In the seventh rabbit, which was killed at the end of twenty-one days, and in the eighth rabbit, killed at the end of thirty-eight days, the same observations were made practically as in the eighteen day rabbit. It was perfectly evident that if the cut structures of an abdominal wound are properly sutured at the time of the operation any supporter applied after the period of repair has passed are superfluous as far as prevention of hernia is concerned, and on the other hand, if any weak point remains as a result of imperfect suturing, a supporter is useless in the way of helping out the defect.

The tiny depressions left at the site of sutures were the weakest points in the abdominal walls of the rabbits, and in the human species any little portion of abdominal wall that was not perfectly united would in the same way remain as the weak point.

Several years ago, before I had engaged in abdominal surgery, it was my fortune to be in a position to see numbers of herniæ that had followed abdominal operations by different operators, and I afterward learned that these cases occurred in the practice of men who employed the single suture for all structures of the abdominal walls. I adopted very early the plan of suturing the separate structures of the wound separately and as a result have never had a hernia follow a laparotomy. If one ever does follow I shall suspect that I may have been in a little too much hurry at the time of the operation. One or two of my acquaintances who use the single suture have not had herniæ follow, but they employ a large number of the single sutures and place them very closely together.

The plan of suturing that I have followed consists in first suturing peritoneal margins together with catgut that is absorbed in one week. The next tier of sutures is composed of catgut that is absorbed in eighteen days, and this series of sutures is employed for very close approximation of the muscular and fibrous structures. The third tier of sutures closes the skin wound and is composed of catgut that is absorbed in seven days, but if the patient is very fleshy a catgut that remains for eighteen days is again used. My patients, as a rule, are allowed to get out of bed on the seventeenth day after laparotomy, and they never wear supporters in the idea of preventing hernia. If my patients find comfort in wearing any sort of bandage for general support, they are allowed to wear what they please.

After operations for the removal of the vermiform appendix, I now employ four tiers of sutures, the extra tier of catgut being used for the superficial fascia, which is an extremely important structure at the site of this operation. I do not propose to have any of the herniæ that are now being reported as common after appendix operations, and none of the patients are to wear "hernia preventing" supporters after they are out of bed either.

Wounds with Dynamite.—The action of dynamite seems to be almost as chaotic as that of lightning, to judge from an occurrence related in *La Science Moderne*, an abstract of which is given in a recent number of *L'Union Médicale*. A nickel-miner was fishing with dynamite cartridges, when one of them exploded as he was in the act of casting it, and carried away one of his hands. During the twelve hours that it took to convey him to a hospital ship, under a tropical sun, gangrene set in, and he died shortly after reaching his refuge. His body was riddled with communicating subcutaneous channels, and at the post-mortem examination it was found that the nails of the lost hand, having been detached, had acted as projectiles, and were found near the spinal column in the thoracic region.—*New York Medical Journal.*

MY OPERATIVE EXPERIENCE IN "PUS CASES."

BY I. S. STONE, M.D.,
SURGEON TO COLUMBIA HOSPITAL, WASHINGTON, D. C.

The following brief recital of a personal experience includes only cases selected from those occurring in my service at Columbia Hospital during the past year. In that time twenty-five cases have been referred to me for operation in which pus in varying amounts was found in the pelvis or abdomen. It will be therefore understood that this is not an account of my "year's work in gynecology," for I shall not mention other surgery for the present. Of these twenty-five cases three have died. But if I add to these the remainder of my pelvic cases I would have nearly fifty without added mortality. I shall limit myself to the consideration of these pus cases alone and shall not mention oöphorectomy, ovariotomy or any other surgery. The organic law of the Columbia Hospital demands that all cases requiring a laparotomy shall be submitted to a consultation of the visiting staff, composed of four surgeons, two of whom are obstetricians and two are gynecologists. It may therefore be taken for granted that only severe cases are treated surgically and unnecessary operations are not performed.

In all of my cases a cause was clearly found for the pathological condition. In about two thirds of the cases, sepsis following abortion or delivery at term, proved the cause. The remainder were due to gonorrhœa. In all of my post puerperal cases the acute stage had passed, and it is impossible to say just how many were due to infection by gonorrhœa, or to that from other sources. One of my cases of post puerperal infection followed rupture of the uterus after labor or during the after treatment. Five cases were the victims of puerperal septicæmia continuing for four, five, and in one case eight months, following delivery at term. These women looked like victims of phthisis, or malignant disease. Six cases had pelvic abscesses of all sizes to a quart of pus following upon gonorrhœa for from one to twelve or more months.

One of the most interesting cases was the result of specific infection of a bicornate uterus.

Clinical History.—The account given by the patient of her suffering, is generally sufficient to indicate suppuration within the pelvis. They tell of pain, peritonitis, rigors and sweats, and slow getting up after delivery. These symptoms demand that a careful pelvic examination be made which will always clear up the diagnosis. Strange enough it is, yet true, that quite a large proportion of these patients claim that they were treated for neuralgia, malaria, etc., and that no pelvic examination had been made by the attending physician.

Of all symptoms pain is the most indefinite. It is always present in varying amount, but is never a positive indication of the extent of disease. Many neurotic patients have far greater tenderness in the ovarian region, and complain more of pain than is elicited in the examination of a pelvic abscess. Neither is the temperature an indication of the extent of disease. We may see a temperature of 100° in morning and 102° in afternoon in a patient with pelvic abscess containing a pint of pus, and with extensive bowel adhesions. Per contra, a small pyosalpinx may cause a rise to 104° P.M. Some of my cases of pyosalpinx with adhesion had no rise of temperature. But we must never underestimate the important information given by the thermometer, for continued high temperature in these cases means trouble ahead for both patient and operator.

The pulse will furnish much information.

A pulse of 140 or above with a continued high temperature means an ill patient. It means a difficult and dangerous surgical operation where all the resources of the well appointed hospital, and the best surgical skill may be required to meet the many possibilities of such surgery as is necessary to save life. The information gained by the pelvic examination of these patients is final and most satisfactory as a rule. My plan is first to examine without, and afterward with, an anæsthetic. Rarely it is important to learn more than to be sure that pus is, or is not, present—or rather, is an operation demanded or not? I fail to see any benefit to be derived from nice distinctions about diagnosis. Such refinements are absurd to the practical surgeon. The preparation of the patient includes tonics, laxatives and good food, cleanliness, cheerful surroundings. I prefer always to give quinine at once after admission, to watch its effect upon the temperature. Not infrequently a rise of temperature during convalescence after operation is promptly reduced by the administration of quinine, showing a malarial complication. So much has been said about expedition, and everything else a surgeon must have in mind during an operation, that I shall not refer to this part of my method or opinions. Each one has an individuality peculiar to himself and cannot be a surgeon without this *sine qua non*. Drainage is just as important as it ever was in many cases, but the glass tube reaches a limited area and I am finding great comfort and satisfaction in the use of the gauze drain. It has done good service in every case, and it is scarcely necessary to say that it is used in very severe cases.

Hæmorrhage has never been difficult to control. Every important vessel can be brought into view by means of the Trendelenburg posture, which I find very useful. Flushing the abdominal cavity is also just as beneficial as Joseph Price claims it to be. I find myself occasionally doing without it, since I use the Trendelenburg posture for difficult cases. I quite agree with those who claim that it rarely if ever does harm. It is also occasionally necessary to use aristol as suggested by Dr. Robert T. Morris of New York. After separating formidable adhesions it is very desirable to prevent the reforming of these dangerous impediments to the peristaltic action of the intestines. Aristol may be freely sifted over these surfaces without fear of harmful result. In the after-treatment my method is to sustain all the cases of laparotomy for pelvic abscess by giving food and stimulants by rectum at once, and by the mouth just as soon as they can be borne. Patients must not be allowed to remain the usual *twenty-four hours without nourishment.*

In the treatment of nausea, if persistent, I resort to lavage in any case. It is the most potent agent for good I have ever seen tried. Of course the usual sip of hot water, and even creasote may be tried, but when these fail it seems unkind to try every drug with a reputation as a composer of sick stomachs. A clean stomach is often in my experience the forerunner of an appetite. With soap and water for the hands, clean dressings, instruments, sutures, etc., all suppuration can generally be avoided in the abdominal wound. Chemical antiseptics, I do not find essential. The only use these agents have in my laparotomies,is where the hands of assistant or operator need to be quickly cleansed during an operation, and where the usual time and care cannot be given them. Clean boiled water is used without any chemical whatever. Suppuration may generally be avoided in all cases where the abdominal wound is not infected by pus or serum removed. The greatest care bestowed upon hands, and instruments, will not prevent infection of the wound, if fetid pus from a suppurating dermoid cyst, or even that from certain pelvic abscesses, comes in contact with it. It has never been my misfortune to have a ventral hernia follow a laparotomy. All operations done for pelvic abscess or pyosalpinx have been completed. In one or two cases very small ovaries were not found even after careful search. They were, if present, too small to have any pus in them. No exploratory operation for pus has been undertaken by me.

The following case is reported to show how fatal an attack of gonorrhœa may prove.

Case 15.—Mrs.—— had contracted gonorrhœa from her husband and came to my office for treatment. She was at once sent to the hospital where in a short time the vaginitis was cured. But in two weeks she had cystitis, then nephritis. An ovarian abscess on left side holding a pint of pus rapidly formed. Operation was refused at first and was only done as a last resort. Patient did well for three days, then came suppression of urine, uræmia and death on fifth day. The autopsy showed a perfect condition of the pedicles and peritoneum. No peritonitis. Death due to nephritis in less than five weeks after infection from gonorrhœa.

The next case, also fatal, is cited to show how easily some patients succumb to shock. Also how sepsis following abortion may continue indefinitely and not recover.

Case 26.—Miss——, age 19, had an induced abortion one year previous to her admission to the hospital. History of pain in pelvis, gonorrhœa, inflammation of bowels, purulent vaginal discharge, large mass in right and smaller one in left ovarian region; uterus fixed and low down in the pelvis. Operation difficult, and bowel much injured in one place but returned hoping for good results. Patient did badly from the start. Bowels refused to respond to salines. Distension. Again resorted to irrigation. Pulse did not recover its tone. Death on third day. I am unable to say why this patient could not stand the shock of operation. She had the very best care during the after treatment.

The next case (No. 18), I report to show that a perfectly satisfactory operation may fail of its object, partly owing to lack of care in after treatment.

Mrs.—— had puerperal septicæmia followed in—— by a large pelvic abscess extending to umbilicus at time of section. High temperature to 104. Pulse 130. Everything fixed in pelvis and lower abdomen. During the two weeks She remained in the hospital prior to operation she grew steadily worse and a bad result was not altogether surprising. The difficulty of the undertaking can only be known to those who have wrestled with these formidable cases. The operation required about an hour,and very much pus escaped and was washed out of the cavity. Although the operation was well done, as shown at autopsy, she had severe shock, and in absence of nurse for a few moments from the room the night after the operation, arose from her bed with the glass drainage tube in position. I consider this case a sacrifice to the unfortunate theory of some of our leading surgeons who say starve these cases for 24 hours. This patient needed food and stimulants from the start which she did not get until too late.

The next case (No. 17), in many respects like the last, only following gonorrhœa instead of puerperal septicæmia.

A woman, age—— and married, had symptoms of pelvic abscess for—— before admission to the hospital. After admission her condition grew rapidly worse and a tumor now reaching nearly to the umbilicus was of uncertain character. Her temperature and pulse gave positive evidence of the severity of the disease and of the necessity for operative treatment. I pause here to remark that to have aspirated any of these cases through the vagina, would have reached only a small area of the disease, and would have evacuated very little of the accumulated pus. In opening the abdominal cavity the omentum was, as is so often the case, adherent to everything in its reach. It was difficult to find an opening or crevice anywhere to even begin the work of separation and enucleation. Many visitors present, among others the hospital staff and Professor Lovejoy of the Georgetown Medical College, were invited to inspect the tumor after the abdomen was well opened and omentum removed,but without any definite conclusion. It is well to be frank, and hence I cheerfully admit that I was unable to say with my hands upon the mass just what was within. The separation proceeding,however, soon revealed abundant pus, which gushed out freely, and although the operation was difficult, was well done, and after much anxiety for a few days she made a perfect recovery. The temperature and pulse chart of this case is very interesting. Both were high before section, and very gradually recovered afterwards. A striking feature of these pelvic abscesses is the very small amount of debris found and removed. The remains of this woman's tubes and ovaries give no conception of the kind of surgery required to complete the operation.

The separation of adhesions in this case was done without tearing the bowel, and the abdominal wound healed nicely and without suppuration.

Septic Disease in Uterus Bicornus.—Another interesting case, No. 22, occurred in a young negress following gonorrhœa. When first admitted she appeared to have a fibroid tumor reaching the umbilicus, with suppurating tubes and ovaries. High temperature, quick pulse and other signs of pelvic disease present. The case was considered by the visiting staff so undesirable a subject for operation, that she was allowed to remain for several weeks under observation, during which time she gained somewhat, and a favorable time was selected after her condition had improved. The operation was nearly completed before the discovery was made that I had really removed the tube, ovary and a portion of the bicornate uterus. This was not extremely difficult save for the broad pedicle, which was very deep down in the pelvis, and so closely attached to the uterus as to cause some delay. When the left side was undertaken the real nature of the case was understood, and fortunately no serious disease existed, and operation was not required upon that side. The sac contained very thick and peculiar, ill-smelling pus. Recovery uneventful save for a slight dementia which continued a few days only, and was of the happy or ecstatic variety. She proved quite entertaining to her nurse, and discoursed tuneful melodies without number. Another interesting case recently treated deserves mention. Had septic metritis, high temperature, etc. A month or six weeks previously had child at term, followed by septicæmia. A mass in right ovarian region supposed to be Fallopian tube. Temperature 102°, pulse 120. Patient and consultant refused to assent to an operation until several weeks had passed, during which time she steadily grew worse. Operation difficult from the start. Omentum glued to everything, and dipping down over right appendages, was inserted in the wall of the uterus just above the attachment of the bladder. When scooped out, a large opening was found into the uterine cavity, through which the index finger was freely passed. Infection had entered the pelvis and abdomen through this channel. The intestines were badly torn in separating adhesions, requiring many sutures before they could be returned. I was anxious about the patient until her bowels acted, for fear that I had closed the bowels too tightly. Her convalescence was uninterrupted after her bowels acted, fifty-two hours after section. I should have remarked that I packed this patient's pelvis with gauze, and dusted aristol over intestines where previously adherent. Gauze was used all around the uterus, for fear of infection through the uterine wound, as it could not be entirely closed with sutures, owing to the friable nature of the tissues. Still more gauze was passed down in the vicinity of the right broad ligament, where the intestines had been very adherent. The glass drain discharged but little fluid, while the gauze poured out an abundance.

These formidable cases are fortunately, as a rule, safe for full and complete recovery, after the danger incident to the operation has passed. Thus far, I have more satisfaction with this surgery than any other. It is always best to complete the work well, when once undertaken. Otherwise the old method of puncture through the vagina will be again heard from. In this connection I wish to say that I have seen at least four cases where puncture through vagina reached pus in the broad ligament, and was followed by an apparent cure. But if any practitioner will witness one of these sections, and see how perfectly thin and healthy the broad ligament remains after all adhesions and disease have been removed, he must indeed be hard to convince if he still believes in the old theory of "cellulitis" as explaining these pelvic masses.

Finally, and in conclusion, I must refer to the minor cases which have been operated upon, and which are abroad in the land by scores, without recognition. One case, No. 20. W. had been married sixteen years; one conception; pelvic disease ever since. Pain, retroflexion, sterility. Treated for months at a time by various physicians. Finally, after nearly two months more of treatment under my own supervision without result, section. Two large pus tubes like sausages. No trouble whatever in convalescence.

Another patient (Case 12), unmarried, had gonorrhœa some months before admission to hospital. Vaginitis treated. Pain in both ovarian regions, rapidly growing worse. Section. Plenty of pus in ovaries and tubes. Perfect recovery.

Another (Case 34) contracted gonorrhœa from husband. In four weeks pyosalpingitis of right side, involving intestine. At time of section free pus poured out of left tube. Fimbria of right tube implanted upon intestine like a placenta; ovarian and tubal abscess. Bowel gave much anxiety, as it was badly necrosed. Gauze packing and drainage after flushing. Perfect recovery. The length of this article forbids further mention of these very interesting cases.

THE PATHOLOGY OF INTESTINAL OBSTRUCTIONS FOLLOWING ABDOMINAL AND PELVIC OPERATIONS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June 7, 1892.

BY WILLIAM EASTERLY ASHTON, M.D.,
PROFESSOR OF GYNECOLOGY IN THE MEDICO-CHIRURGICAL COLLEGE OF PHILADELPHIA.

Notwithstanding the brilliant results which have been attained in modern abdominal and pelvic surgery there is still much to learn and to improve upon in our operative technique before some of the distressing after results of these operations are prevented or at least rendered less frequent. Among the most important of these post-operative complications I would include intestinal obstructions.

An enormous amount of literature has been written upon acute intestinal obstruction as a surgical disease and the subject is, very properly, receiving the attention it deserves in our medical societies, but, as yet, little has been done toward solving the problems suggested by bowel obstructions following abdominal and pelvic operations. It is, therefore, my purpose in this paper, which I have the honor of presenting before this Association, to enter into the pathology of these obstructions and to discuss such views of the subject as my own experience and that of other surgeons may suggest.

In discussing the pathology of bowel obstructions following intra-peritoneal operations I shall limit myself strictly to those causes dependent upon operative interference and not refer to the causes of acute obstruction from the standpoint of a surgical disease.

I shall classify the causes of post-operative obstructions as follows:

1. Adhesions between the intestine and raw surfaces.
   a. To an omental stump.
   b. To denudations of the pelvic and parietal peritoneum.
   c. To the edges of the vaginal wound following a supra-pubic or a vaginal hysterectomy.
   d. To a pedicle.
   e. To raw surfaces on the intestinal wall.
2. Paralysis of the intestines.
3. Local spasm of the intestines.
4. Impacted fæces
5. Bands of inflammatory lymph.
6. Adhesions between coils of intestine or between the gut and neighboring parts due to a traumatic inflammation.
7. Kinking or twisting of the intestine due to a faulty technique.
8. Including the intestine within the loop of an abdominal wall suture, or between the edges of the belly incision.
9. Slipping of a coil of intestine through a slit or an aperture.

Adhesions Between the Intestine and Raw Surfaces.—By far the greater number of bowel obstructions are due to this cause. A knuckle of gut becomes attached by an adhesive inflammation to a denuded surface and a kink results and an obstruction of the bowel follows. Naturally the question will be asked, how do we explain the fact that so few cases of obstruction occur from this cause when there are so many bad pelvic cases requiring the separation of extensive adhesions? My answer is, that kinking does not necessarily follow the fixation of a knuckle of intestine unless the gut adheres in an abnormal position. In other words, if the normal position of a coil of intestine is near the position of the denuded surface to which it adheres obstruction will not as a rule follow. Furthermore, I believe that many of the cases which die after abdominal and pelvic operations, and the cause of death is ascribed to peritonitis, are in reality undiagnosed bowel obstructions.

The following cases present points of great interest in connection with this class of obstructions.

Case 1.—Reported by Meredith.[1] Section for double cystoma with extensive adhesions. *Secondary Section*, eighth day. The peritoneum was intensely red and congested, evidently in the first stage of acute inflammation. "Attention was attracted to a coil of greatly distended small intestine which was badly kinked and obstructed in consequence of the traction exerted upon it by a portion of the ligated omentum which was closely adherent to its surface." There was no other obstruction. The patient recovered.

Case 2.—Reported by Krug.[2] Section for double pyosalpinx and ovarian abscesses. Adhesions especially extensive behind uterus. Irrigation and drainage. *Secondary Section.* Fourth day. Signs of beginning peritonitis. A portion of the descending colon was found glued fast as an angular loop to the posterior surface of the uterus. The patient recovered.

---

[1] London Lancet, 1886, p. 64.

[2] Amer. Jour. of Obstet., 1890, xxiii, 1371.

Case 3.—Reported by Ahern.[3] Section for large cyst of right ovary. Adhesions to brim of pelvis on left side and to sigmoid flexure. Raw surfaces two in number, and ½ of an inch in diameter each. No drainage. *Secondary Section.* Ninth day. Upper part of small intestines congested and distended. Adherent to pedicle and to both denuded surfaces. Below the adhesion the bowel was contracted. The coil of intestine at point of adhesion formed an acute angle. The patient recovered.

Case 4.—Reported by Anderson.[4] Section for ovarian cystoma. Adherent to parietal peritoneum just above the position of the cæcum. *Secondary Section.* Twentieth day. Coil of small intestine adherent to raw surface just above the position of the cæcum. Below the adhesion the gut was collapsed, above distended. The patient recovered.

Case 5.—Reported by Coe.[5] Vaginal hysterectomy. Uterus retroflexed and adherent. Ovarian cyst right side punctured and removed. No ligatures. Two forceps to each broad ligament, and two pairs to bleeding points in utero-sacral folds. Peritoneal wound left open. Tampon iodoform gauze. *Section.* Fifth day. A loop of small intestine adherent to the right edge of vaginal wound. No peritonitis. The gut was distended above the adhesion and contracted below. The patient died next morning from shock.

The following cases of "ileus after vaginal extirpation of the uterus," quoted by Coe from a paper by Reichel[6] are of great interest.

Case 1.—Section. Seventh day. The lower part of the ileum was attached to the edge of the vaginal wound. Gut above distended. No peritonitis. Patient died on the table.

Case 2.—(Olhausen.) *Section.* Ninth day. A coil of ileum adherent to edge of vaginal wound. The gut was bent at an angle. Died in 24 hours. *Post mortem.* Diffuse peritonitis. *Two other coils found attached to edge of vaginal wound.*

Case 3.—Collapsed and died on the eighth day. *Post mortem.* Coils of intestine adherent to edge of vaginal wound, the gut above greatly distended. The large intestine contained fecal matter, therefore, the obstruction was *not* complete. No general peritonitis.

The four following cases of obstruction consequent upon vaginal hysterectomy are also quoted by Coe.

Case 1.—Bakelmann's patient.[7] Died on seventh day. *Post mortem.* Lowest part of ilium adherent to edge of vaginal wound. Gut distended and bent at an angle.

Case 2—Leopold's patient.[8] Death on fourth day. *Post mortem.* Two coils of intestine adherent to edge of vaginal wound. The gut bent at an angle.

Case 3.—Landau.[9] *Section*. Seventh day. Adherent gut to edge of vaginal wound. Died next day.

Case 4.—Coe's patient.[10] *Section.* Second day. Two or three coils of illim adherent to edge of vaginal wound. Gas escaped per anum after they were detached. No peritonitis. Death in four hours.

These cases illustrate in a forcible manner the explanation and dangers of obstructions due to raw surfaces. In every one of the abdominal sections the obstruction occurred at a point where adhesions were separated at the time of operation. Again, in every instance, the intestines were fixed in an abnormal position and at the point of fixation formed a more or less acute angle. In the case reported by Krug where he found the descending colon "adherent as an angular loop to the posterior surface of the uterus" we have an instructive illustration of these points. The cases quoted of obstruction following vaginal hysterectomy, also demonstrate clearly the cause of bowel fixation and kinking dependent upon an adhesive attachment of the intestine to a raw surface.

The practical operative lesson all of these cases teach us is, that when we perform a secondary section for their relief we know where to look for the seat of obstruction if we have kept in mind the position of denuded surfaces made at the time of the original operation.

Paralysis and Local Spasm of the Intestine; Impacted Fæces.—As the pathology of all of these causes of obstruction is the same, I shall discuss them under one heading. First, however, I shall cite some cases illustrating this class of intestinal blocking.

Case 1.—This case occurred in my own practice. Section for double pyosalpinx with slight adhesions. Irrigation, but *no drainage. Death on fifth day. Post mortem.* The small intestine, for a distance of 8 inches from the ileo-cæcal valve, was *tightly* contracted, causing an absolute obstruction. Above the contraction the gut was greatly distended. At the seat of *constriction* the bowel was red and congested, but *no lymph* was found. The *abdominal cavity* was dry. *There were no adhesions.*

Case 2.—Reported by Baldy.[11] Supra-pubic hysterectomy; extra-peritoneal treatment of the stump. *Secondary section.* Sixth day. *Intestinal evacuation* and drainage. Death in twenty-four hours. *Post mortem.* Intestines free, "but in one or two places had contracted so as to feel like hard cords."

Case 3.—Reported by Baldy.[12] Section for double pyosalpinx. Inflammation of some of the pelvic loops of intestine. *Secondary section.* Fourth day. Bowels enormously distended. Intestinal evacuation and drainage; death in twelve hours. *Post mortem.* "There was nothing abnormal found excepting the peritonitis affecting the coils of intestine *in the pelvis. There was a slight adhesion of these* coils to one another."

Case 4.—Occurring in my own practice. Section for chronic inflammation of the appendages. Dense pelvic adhesions. *Secondary section.* Twentieth day. Small *intestines* somewhat distended; *no evidence of peritonitis or pus.* The descending colon was tightly packed with hard fæces from the splenic to the sigmoid flexures. Bands of lymph constricting slightly the bowel near the sigmoid. The patient recovered.

The true explanation of obstructions due to local spasm or paresis of the bowel will, most probably, be found in a study of the influence of various stimuli upon the nerves controlling intestinal peristalsis. The intestinal walls contain an automatic motor centre—the plexus of Auerbach—which influences the peristaltic action of the bowel. "If this centre is not affected by any stimulus, the movements of the intestines cease—comparable to the condition of the medulla oblongata in apnœa. The same is true —just as in the case of the respiration—during intrauterine life, in consequence of the fœtal blood being well supplied with O. This condition may be termed aperistalsis. It also occurs during sleep, perhaps on account of the greater amount of O in the blood during that state. All stimuli applied to the plexus myentericus increase the peristalsis, which may become so very violent as to cause evacuation of the contents of the large gut, and may even produce spasmodic contraction of the musculature of the intestine. This condition may be termed dysperistalsis, corresponding to dyspnœa. The condition of the blood flowing through the intestinal vessels has a most important effect on peristaltic movements. The continued application of strong stimuli causes dysperistalsis to give place to rest, owing to over-stimulation, which may be called intestinal paresis or exhaustion."[13]

With these facts before us concerning the effects of the absence or the presence of stimulation upon intestinal peristalsis we are able, most probably, to explain the pathology of these obstructions. For the first twenty-four or forty-eight hours after an abdominal section the intestines are in a condition of aperistalsis if the case be doing well. There are several factors concerned in bringing about this state. In the first place, the preparatory treatment of the bowels with salines, the liquid diet and the absence of food after section leave the intestines comparatively empty, thus removing the intestinal contents as a factor in stimulating peristalsis. Again, the rest in bed for two or three days before an operation, and the enforced quiet afterwards, add largely to the absence of intestinal activity. This condition is not only observed immediately after an abdominal section, but also after parturition or, in fact, in all cases in which the patient is required to lie quietly in bed for some time. The well known fact that changing the position of the patient in bed relieves tympany in some cases, and favors the downward movement of gas, shows the effect of exercise upon intestinal peristalsis.

The causes of operative stimulation of the intestines are: exposure to the air, lowering of the temperature, bruising, healing of denudations, peritonitis, operative procedures, irritating fluids, septic materials, and a neglect to thoroughly empty the bowels prior to operation.

We have found that dysperistalsis and paresis depend upon the same cause, namely: an irritation of the motor centres of the intestine, but that the intensity and duration of the abnormal stimulation alone determines the difference between the two conditions. For example, a simple congestion of the intestinal blood-vessels would most probably, even if long continued, result in a condition of dysperistalsis, while a severe inflammation, on the other hand, would cause a state of paresis.

In cases Nos. 1 and 2 there was a condition of intestinal dysperistalsis present, causing the obstruction. In both cases, at the beginning, this condition alone existed, but subsequently paresis of the gut above the constriction occurred, due to the continued effort made by the intestine to push its contents beyond the obstruction. The increased amount of gas and fluid in the bowel also aided in producing exhaustion, as they were necessarily a source of continued irritation. In case No. 1 the intestinal spasm was probably the result of the congestion, which was practically limited to the seat of constriction in the bowel. The cause of this congestion is difficult to determine. Possibly it may have been due to the irritation produced upon the intestine by the pus which escaped when the tubes were delivered, or the bowel may have been bruised during the operation, and a traumatic peritonitis was developing at the time of death. In case No. 2 the notes of the post-mortem examination were too superficial to be of any value in determining the cause of the nodulated condition of the intestines. Case No. 3 was clearly one of intestinal paresis due to peritonitis. The adhesions which were found between coils of the intestine after death were evidence that the peritonitis, which had existed at the time of the operation, had continued.

Case No. 4 is of especial interest. The patient had a bowel movement in forty-eight hours, and everything was doing well until she fell out of bed in her sleep on the third day. Now what had happened to bring about an obstruction due to fæcal impaction after this accident? I believe that the fall caused a traumatic peritonitis which resulted in paresis of the colon, and while the bowel was in this condition fæcal accumulations occurred. After the intestine had regained its normal activity, it was then unable to empty itself on account of the great amount of fæcal matter which had collected. In addition to this want of power in the gut, there was also more or less constriction, from bands of lymph, at the sigmoid flexure, which rendered the downward passage of the fæces difficult.

Bands of Inflammatory Lymph.—As the result of intraperitoneal inflammation following abdominal and pelvic operation, lymph is poured out upon the intestines, and coils of the gut become more or less adherent to each other. As a rule, no bad results ensue, but if the adhesions destroy the normal relations existing between the coils, or a knuckle of gut is constricted by a band of lymph, then kinking or strangulation follows. These obstructions do not manifest themselves early after operation, because no serious interference to the movements of intestinal fluids occurs, usually, until the bands of lymph begin to organize and to contract. Montgomery[14] reports an interesting case of volvulus caused by bands of inflammatory lymph. Five weeks after the original operation, for peritonitis, symptoms of obstruction came on, associated with fæcal vomiting. "The intestines were found matted together, so that over a yard of small intestine had to be forcibly liberated from extensive adhesions. The muscular coat was torn through at a number of points; a distinct twist was found in the small intestine, which was readily overcome by separating the bands of adhesions." The patient made a good recovery.

Adhesions between Coils of Intestine or between the Gut and Neighboring Parts, due to Traumatic Inflammation.—These adhesions have always been a subject of great interest to me. They result from an irritation of the serous membranes caused by the exposure of the intestines to the air, to lowering of their temperature, to handling or to necessary manipulations or operative procedures. This class of adhesions is, in my experience, a necessary sequence to all intraperitoneal operations. In fact they are, I might say, the opprobrium of abdominal surgery, for it must be indeed rare to have an abdominal operation not followed by more or less fixation of the viscera. In my experimental work upon the lower animals this fact has time and again forced itself upon me. For example, I have taken a perfectly healthy dog and performed upon the animal a lateral anastomosis without resection. At the time of operation not more than 10 inches of the bowel were exposed through an incision in the belly wall less than 2 inches in length, and every precaution was taken in the operative technique. Yet notwithstanding these facts, when the animal was killed in three weeks, after making an uninterrupted recovery, the intestines were so matted together that it was with the greatest difficulty I was able to separate the seat of anastomosis from the adherent coils of gut. This has been my experience, without an exception, in all my work upon the lower animals. I have seen numerous illustrations of these traumatic adhesions in the human subject revealed during a secondary section or a post-mortem examination. At an autopsy recently held at the Philadelphia Hospital upon a woman who had died three weeks after a supra-vaginal hysterectomy from disease of the kidneys, the intestines were found to be extensively matted together. The hysterectomy was a very simple operation, without adhesions; the abdominal incision was small and there was no exposure of the intestines, and yet, after death, extensive fixations of the gut were found. It is a very common experience, in performing a secondary section, to find the gut or the omentum adherent to the parietal peritoneum at the site of the original abdominal incision. This fact is so well recognized that great care is always taken in reopening the abdomen to cut to one or the other side of the cicatrix, in order to avoid the danger of wounding a knuckle of adherent gut. Fortunately traumatic adhesions, as a rule, are not followed by fatal results, as they do not cause kinking or twisting of the gut. They do, however, not infrequently cause remote troubles by giving rise to colicky pains and more or less tendency to constipation.

---

[14] Philadelphia Hospital Reports, Vol. i, 1890.

Kinking or twisting of the Intestine due to a Faulty Operative Technique.—These obstructions are not the result of adhesions, but occur after anastomotic operations upon the alimentary canal, or after the repair of bowel lesions. For example, a coil of intestine may be kinked or twisted by placing it in an abnormal position in making an anastomosis. Or, again, the bowel may be torn transversely while separating adhesions during an operation, and, if the opening be large, suturing the tear may result in a fatal obstruction from kinking. Tears in the wall of the bowel which are longitudinal to its long axis may be safely closed with sutures, even if it is extensive, but a large transverse opening into the gut will almost certainly cause a kink if sutured.

Including the intestine within the loop of an abdominal wall suture or between the edges of the belly incision.—At first sight these causes of bowel obstruction may appear to the surgeon as being extremely unlikely, or at least very rare. Yet, if we will recall to mind our own operations, as well as those of other surgeons, I think all of us will be struck by the fact that such an accident is liable to occur when the abdominal incision is closed. There is but little danger, I admit, of including a loop of intestine when the belly wall sutures are introduced, as the abdominal contents are protected by a gauze pad or a flat sponge, but it is when they are tied that the accident is likely to occur. After the pad or the sponge has been removed the intestines come in direct contact with the loops of the sutures and press up, more or less, between the edges of the abdominal wound. Naturally, therefore, it is next to impossible for the surgeon to know positively that [illegible] instance, the intestine [illegible] a portion of the gut has not been caught when the sutures are tied. Of course, if the gut has been fastened to the abdominal incision no immediate result will necessarily follow unless the lumen of the intestine has been obliterated, leakage occurs or kinking takes place. Consequently, we are not aware, in the majority of instances, that such an accident has occurred. Or, again, if the accident be followed by a fatal result, its true nature cannot be determined except by an autopsy.

Shively[15] reports an extremely interesting case in which death occurred five or six years after an ovariotomy from a bowel obstruction, which was the remote result of the fixation of the intestine to the abdominal incision. After the original operation the patient was always "greatly troubled with constipation and frequent attacks of colic." She was obliged to use strong cathartic pills to keep her bowels open. On August 8, 1883, she was taken ill. "She said she was ill with an attack of colic," August 11. Fecal vomiting. Death.

Post mortem.—"At the lower end of the line of the belly cut, a discolored spot, half the size of the hand was seen. The bowel was here adherent. There were also extensive adhesions of the intestines to the sides and posterior wall of the abdomen, thus preventing the appearance of tympany. The intestines and cavity nearly everywhere gave evidence of former inflammation. Also a portion of the ilium (18 inches above cæcum) was adherent to and incorporated with the cicatrix corresponding to the lower angle of the original wound, and that around the short portion between this and the cæcum a loop of small intestine was twice twisted, forming a kind of knot and a complete and effectual barrier to the passage of the intestinal contents."

Slipping of a coil of intestine through a slit or aperture.—This accident may occur from the following causes: 1. The result of adhesions. For example, a band of inflammatory lymph may be so attached that an aperture is formed. Or, again, a coil of the intestine or the mesentery may adhere and form a loop through which a knuckle of gut may slip. I saw an autopsy upon a patient who had died after an abdominal section, where the omentum was found adherent to the parietal peritoneum by two distinct attachments, thus forming an opening through which the intestine might readily have passed. An instructive point in this case lies in the fact that the adhesions were caused by two omental stumps which were left after the omentum had been ligated for adhesions at the operation. Larkins[16] reports a case in which death resulted from an obstruction following a jejunostomy. The original operation was performed for a cancer of the stomach, but in less than three months afterwards he did a jejunostomy on account of obstructive symptoms developing. The patient then did well for about two months when intestinal obstruction again occurred and death resulted.

Post mortem.—"There was a firm adhesion between the jejunum and the incision in the abdominal wall made in performing the gastro-enterostomy. The portion of jejunum taken in the jejunostomy was only two to three inches above this adhesion. The piece of jejunum between these two attachments to the abdominal wall formed a little loop, and between this loop and the parietes the upper segment of the jejunum had slipped. It was firmly nipped. The intestines above were greatly dilated and ruptured just above the seat of constriction; the intestines below were contracted."

2. A faulty method of dealing with tears or incisions through the mesentery. Thus, if the mesentery be torn during the separation of adhesions and the tear is not closed, and its flaps are not well sutured after the resection of the bowel, a coil of intestine is liable to slip into the opening and become nipped. 3. The slipping of a coil of intestine through the vaginal wound after complete removal of the uterus. 4. A knuckle of gut pushing its way through the intestinal loop formed in making a lateral anastomosis without resection. 5. From a fixation of the gall bladder to the abdominal incision. 6. From openings made through the transverse meso-colon and the great omentum to facilitate

the attachment of the bowel to the stomach in performing gastro-enterostomy. In a case[17] of cancer of the pylorus in which this was done, the post-mortem examination showed that "almost all of the intestines were in front of the great omentum, having prolapsed through a hole in the transverse meso-colon and great omentum. There had passed all of the jejunum and the ilium to within four inches of the ileo-cæcal valve."

2011 Walnut Street.

SOCIETY PROCEEDINGS.

Gynecological Society of Boston.

Regular Meeting, held June 9, 1892.

The President, Augustus P. Clarke, M.D., in the Chair.

Dr. A. H. Tuttle, of Cambridge, read the following paper on

ANIMAL LIGATURES AND SUTURES, THEIR VARIETY, PREPARATION AND USES.

Surgeons are divided in their opinions upon the relative merits of various sutures. Silk, one of the first materials to be employed, is still the most popular, and many operators employ it almost exclusively. In the large surgical clinics throughout the world it forms the chief material for closing all kinds of wounds. Catgut and animal ligatures are comparatively of recent use, and offer the special advantage of being absorbed by the tissues, which makes it unnecessary to remove them. In all wounds which are aseptic, these sutures may be used, buried deep in the tissues, without piercing the cuticle or appearing upon the surface of the skin, the line of incision closed with collodion dressing or, in certain localities involving mucous surfaces, with the compound tincture of benzoin, containing a little iodoform, and the wound will be entirely healed at the end of five or six days, without evidence of suppuration. Does not this seem to be an ideal method? There are certain cases, however, where this cannot be accomplished, and where the healing in part is attended with suppuration, *i. e.*, recovery by second intention. In such cases imperfect results are liable to follow the employment of animal sutures, since they will be softened, absorbed, and give way before healing is effected. Gaping of the wound will then result, which would have been prevented had a more permanent suture been used. In abdominal operations it is better to use animal sutures entirely, even if pus is present, since it will remain long enough to do all that is required of it, and it is less liable to become a foreign body, with subsequent sinus formations, and slow cure. In earlier times, before the ideas of sepsis, asepsis and antisepsis had taken material form, silk and other sutures were used without any special preparation, and as might be supposed, primary healing in certain localities never took place. No better example of this can be given than the work of [1]Marion Sims upon vesico-vaginal fistulæ. It will be remembered that Sims operated a great number of times, and in fact had perfected his operation, without realizing its success, and it was only after he changed the material of his suture from silk to silver wire, that he succeeded in completely closing the fistulous opening between the vagina and bladder. To Sims, it seemed as though the substance of the suture brought up the balance in favor of success, but viewing the facts through the spectacles of to-day, we can see still farther, and realize that it was not the mere material from which the suture was constructed, but upon its aseptic preparation, that his success was won. It is a simple matter to make a suture of fine silver wire, free from irritating properties, and such measure of cleanliness as most surgeons used in those days, would render a suture of this kind practically aseptic. With silk, however, it is quite a different thing, and although it is easily sterilized by special measures, such as boiling, it would rarely be found free from irritating properties in the condition in which it was employed by the older surgeons. Experience has taught us the truth of these statements, for to-day, by simply sterilizing our suture, we can complete the operation for vesico-vaginal fistula without regard to the substance of which it is made. The aseptic condition of the suture is of the utmost importance, and if this condition is maintained, the suture, no matter what it be made of, may be placed almost anywhere without causing a great amount of irritation. If buried in tissue, most sutures, metallic ones excepted, will become absorbed, although it may take a long time, according to the material from which they are made. Firm union of parts should never take over ten days, when the union is by primary intention, therefore any substance which is used for a buried suture should be well under the process of absorption by that time, otherwise it will be in the way, and may retard the normal changes of repair. The animal ligature fulfils this requirement as nothing else will. It is owing to this fact that its growing importance depends. From a few, perhaps bold operators who used it at the beginning, there has been a steady increase in number, until now the larger part of the practicing surgeons of our country, and abroad, have come to recognize its value, and employ it. A great deal of opposition has checked its use, because it can only be made aseptic by a most careful preparation, and much of the material delivered from the instrument maker brought sepsis into the wound; furthermore, it may be absorbed too rapidly, and result in secondary hæmorrhage.

[2]Dr. Sims, of New York, objected to its use in operations upon the cervix uteri on the latter account. [3]Dr. J. C. Warren has said, "I would not rest easy if I had tied an ovarian pedicle with catgut until the danger of secondary hæmorrhage was passed." A study of the various methods of preparing catgut, employed by many prominent surgeons throughout the world is sufficient to demonstrate that the great consideration is its aseptic condition, and but little stress is placed upon its being absorbed too rapidly. This then, is really a great gain in favor of the use of animal ligature, since, a priori, its too rapid absorption was the strongest argument against the use of this material. If it would not resist absorption long enough for the wound to be united firmly and long enough for a good strong clot to organize in the larger blood vessels, sufficient to protect against secondary hæmorrhage, it would not fulfil the requirements of a suture, or ligature, and must sooner or later for this purpose become obsolete. The fact that surgeons no longer bother themselves with methods to increase the resisting power of the gut, against the absorbing powers of the tissues indicates very strongly that they no longer fear that effect, and in fact practical experience shows that under the proper circumstances we can depend upon animal ligature to hold until the parts are firmly united. Most of the evil consequences come from the use of septic gut.

[4]Klemm claims that abscess formation takes place frequently in wounds closed with aseptic gut, where all aseptic precautions have been taken; the infection arising during the operation, and developing in the culture medium formed from the dead softened material of the ligature. He says: "It is almost impossible to keep a wound germ free," and thus explains the cause of the trouble. His gut was prepared by washing repeatedly in five per cent. alcoholic solutions of sublimate, until there was no turpidity, and then storing it in absolute alcohol. This gut was exposed to culture experiment, and by this means, determined germ free

---

[17] Larkin, London Lancet, 1891, 11-1222.

My experience has been, and it is the same as my associates, that if asceptic gut, or animal ligature, is placed in an aseptic wound, which is maintained so, that wound will heal rapidly without suppuration, unless the nutrition of the tissues are modified by senile changes, or some other disturbing influence. [5]Reverdin used gut prepared by heat for eighteen months with perfect results. [6]Timothy Holmes says he has had no bad effects from the use of catgut, and [7]Watson Cheyne has seen little suppuration result from the use of this material. Of the last 600 unselected hospital cases operated upon with kangaroo tendon [8]Marcy had suppuration in only two per cent., with one death from sepsis.

[9]Marsh believes that when gut is properly prepared it will cause no more suppuration than silk. If a selection of cases and circumstances can be made, such as filled the requirements of Klemm's experiment, the wound ought to invariably heal without suppuration. Abscess formation after the use of gut was a common thing, and it was due to the septic condition of the suture, but to-day it is, or ought to be, of exceptional occurrence, and the daily experience of those skilled by its habitual use, where the conditions are the fac simile of those in Klemm's experiments, is quite out of harmony with the results of the latter. In the investigations of [10]H. L. Burrell and G. R. Tucker, they found that catgut prepared by immersion in a 1 to 1000 alcoholic solution of corrosive sublimate, contains germs, and could not be relied upon; their explanation was, the hardening of the gut, prior to complete sterilization, shut up the organisms in the substance of the gut, where they were preserved alive, until set free by the swelling of the suture in the living tissues. This may also be the explanation of Klemm's results, at least his method of preparing the gut is practically the same, and open to the same objection; its insertion in the living tissue should be the practical test of its aseptic condition, and not by bouillion or similar cultures. That the great danger in the use of animal ligature is from' its being septic, the result of imperfect preparation, is proven beyond cavil. Not long ago, a patient died in [11]Volkmann's clinic from anthrax, the infection arising from catgut that had been derived from an animal suffering from that disease.

[12]Marcy has reported where several patients were infected almost simultaneously from the same lot of septic gut. Marsh, and many others have reported cases that show this danger, the avoidance of which, depends upon the careful preparation of the gut. Many writers speak of uncertainty of the material, derived from the instrument makers, and point to the necessity of the surgeon preparing his own sutures. The following are some of the methods employed in the preparation of animal ligatures: Sir Joseph Lister [13] made a solution containing one part chromic acid, and 4000 parts of distilled water to which was added 200 parts of pure carbolic acid. In this solution catgut, equivalent in weight to the carbolic acid is placed, and allowed to remain 48 hours. It is then taken from the solution, dried, and stored in 1 to 5 carbolic oil, when it is fit for use.

[14]Macewen prepares his catgut by immersing it in a watery solution of chromic acid 1-5 and adding one part of this to 20 of glycerine. At the end of two months this is removed, and kept for use in 1-5 carbolic acid and glycerine.

[15]Reverdin takes crude catgut, which has not been preserved in fat, exposes it for four days to a constantly increasing temperature until it reaches a maximum of a 140° C., and then places it for a day in oil of juniper, when *it is* stored in alcohol.

[16]Larochette writes, at 90° C., the small gut is spoiled; at 100° C., the largest gut is spoiled, when fat is present, as it is fried in its own grease. If the fat of catgut is removed by ether and bi-sulphide of carbon, the gut will suffer no change, if gradually heated in a large oven to 100° C. I heated to 145° C., for three hours it becomes slightly burned but is strong enough for surgical purposes. When the gu is freed from fat by the use of ether, and sterilized by hea it becomes almost friable and is worthless. He believes 140 C. is sufficient heat to sterilize the gut; he stores it i boiled olive oil, containing 10 per cent. by weight of car bolic crystals. Catgut sterilized by heat is not quite s strong, and is less pliable.

[17]Bryant places crude catgut in a solution of bichlorid 1–1001 for ten minutes, then into a weaker solution 1–100 for 12 to 14 hours; it is then wound on bobbins, and kept i absolute alcohol.

[18]Kocher places the gut in oil of juniper for 24 hours and stores it for use in absolute alcohol.

[19]Partridge severs the gut into one foot lengths, an places it in ether for 5 days; it is then removed and place in Bergmann's solution, corrosive sublimate 5 grains, water 31½ oz., in alcohol sufficient to make one pint, and kept fo ten days; it is stored for use in a solution of equal part of ether and alcohol, saturated with iodoform.

[20]Clinton Cushing uses the best violin catgut strings which are placed in a large open mouthed bottle filled wit sulphuric ether, and allowed to remain 48 hours; whe removed they are nearly white, as the ether takes out th animal oil; they are then placed in a mixture of three part alcohol, and one part juniper oil, with the addition of thre drachms of hydro-naphthol, to each quart of the fluid; th strings are allowed to remain in this mixture ten days, whe they are ready for use.

[21]G. R. Fowler winds catgut on ordinary spools which hav been boiled in soda, and places them in a jar containing on pint of alcohol for every fifty meters of gut; the jar is the placed in a water bath, or milk sterilizer, and the alcoho boiled for one hour. 95–97 per cent. alcohol is used.

[22]Curtillet sterilizes the catgut by heating for one hal hour in a partially closed glass vessel, at a temperature o 284° F., which is gradually increased to 302° F. It is then placed in absolute alcohol, and ready for use. Thus treated, it will remain for an indefinite time, sterile, strong and pliant.

[23]Mass. General Hospital: The catgut is soaked in ethe several days, and is then placed in an alcoholic solution of corrosive sublimate 1–1000. (95° alcohol.) In some cases it is sometimes boiled in alcohol in a closed jar for half an hour, and then preserved in absolute alcohol.

[24]Boston City Hospital: The catgut is allowed to stand for 24 hours in aniline oil and is then heated while still in this oil to 115° C., for 15 minutes. It is then transferred to a 10 per cent. solution in alcohol until it is soft enough for use, and is transferred to a 3–4 per cent. solution of glycerine in alcohol so as to render it less slippery.

(*To be concluded.*)

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1271, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1271, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JULY 9, 1892.

BY-LAW IV OF THE AMERICAN MEDICAL ASSOCIATION.

The Publication of Papers and Reports.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

THE URINE IN NEURASTHENIA.

In a recent number of the *Post-Graduate*, we find the report of a discussion of the clinical values of urinalysis. In it are given the maturer views of Dr. C. L. Dana on that line of investigation in cases of neurasthenia. He has for many years made the routine examinations for sugar and albumen; but lately he has gone more explicitly into the relations of quantity, density and the amount of the phosphates.

A low specific gravity is found in nearly all cases of affection, and the proportion of the solids and of the urine was rather below the normal. But a dense urine may be found in one class of neurasthenics, namely, those who suffer from the lithæmic form. This latter is generally acquired in consequence of overwork, indigestion and hepatic impairment. Then a dense urine, voided in large quantity, and containing considerable proportions of solids, chiefly urea and uric acid. These have already been pointed out by Dr. Dana and others as signs of the neurasthenic state. The discharge of the alkaline phosphates is governed largely by the diet, but the relation to them of the earthy phosphates is important. The author's studies have taught him that an increased proportion *of the earthy phosphates implies neurotic trouble;* and without seeing the person he has been able safely to indicate that the specimen had been voided by a nervous patient. In that other form of neurasthenia, where the urine was dense, there is less proportion of earthy phosphates, growing less and less as the urinary density is increased. When associated with this dense urine there is a little sugar, the quantity of those phosphates is still farther diminished. If under treatment the sugar disappears, the phosphates will return.

A French writer has reported that after epileptic attacks the quantity of phosphates show little change, but that *after hysteria there is an inversion of the* usual ratio existing between the alkaline and the earthy phosphates. Ordinarily this ratio is as one to two and one half or three, but after an attack of hysteria, it may be as two to two, or as three to two, the earthy phosphates are increased while the alkaline phosphates diminish. Dr. Dana has examined the urine of epileptics and in regard to them has verified the statement of the French observer, but he has not yet formed an opinion as to hysterical changes in the phosphates.

THEATRES AND TUBERCULOSIS.

Mr. Henry Irving recently spoke at a festival dinner of one of the hospitals for consumptives in London. He made merry, says the *Press and Circular*, over a letter, written to him by a medical man, suggesting that if the theatres were kept closed the hospitals for consumptives might be reduced one-half. The idea of the letter-writer was that the systems of ventilation of theatres were so villainously bad, that those who subjected themselves to incident exposures to draughts and sudden changes of temperature took their lives in their hands, when going to these places of amusement. The specific cause of tuberculosis may or may not be *propagable in the* various illy ventilated halls where pleasure seekers gather, but there is enough of old-fashioned truth about the belief that many a case of lung-trouble has taken its rise in the "bad cold" that was caught at the theatre. Possibly a subsequent want of care and treatment, together with some mysterious bacillary implantation *at a time when it could do the utmost* harm, have been necessary to convert these cases of "cold" into phthisis, still there may be a justly chargeable contributory element for the theatre to sustain. The question of properly ventilating a place of public resort has been solved time and again by experts in that department, and it resolves itself down into a question of cost. If the money is freely supplied for the purpose, any given building can be adequately ventilated. just as certainly as it can be rendered safe against fire. But the money cannot commonly be spared for these objects—it is required to be spent upon some tower, or pinnacle, or other architectural embellishment.

THE SECOND ANNUAL MEETING OF THE AMERICAN MEDICAL TEMPERANCE ASSOCIATION.

This is the youngest of the National medical organizations that hold their annual meetings in close connection with those of the American Medical Association. It was organized during the session of the latter Association in Washington, May, 1891, and held its next annual meeting at Detroit, June 9, 1892. At the first meeting fifty-six physicians were enrolled as members, and perhaps as many more have been added since. The objects and plan of the organization are nearly identical with those of the British Medical Temperance Association, which has been in active operation several years and now numbers about six hundred members. The meeting at Detroit was held in the hall of the Young Men's Christian Association on Thursday evening June 9, 1892, and was well attended. The President, Dr. N. S. Davis, of Chicago, delivered an address, in the first few lines of which, he stated explicitly the objects of the Association, and then proceeded to point out the fallacy of classing the carbo-hydrates of fermentation or bacteriological production, as the alcohols, along with the carbo-hydrates of vegetable growth, as starch, sugar, oil, gum, etc., and calling them all indirect or respiratory food. His views of the histological, physiological, and therapeutic relations of alcohol were clearly stated and illustrated by reference to the experimental researches which have been prosecuted both in this country and Europe. But as the address in full may be found in another part of The Journal, each reader can peruse it for himself. Dr. T. D. Crothers of Hartford, Conn., read a brief paper on "Heart Failure from the Medicinal Use of Alcohol, Illustrated by Cases"; and Dr. I. N. Quimby, of Jersey City, N. J., read a paper on "Some Dangers of the Use of Alcohol in Acute Diseases." Some of the cases and facts related in these papers were highly interesting and valuable, and their presentation was followed by an earnest discussion concerning the actual value or non-value of the use of alcohol in both health and disease, in which a large number of those physicians present took an active part, and the interest was sustained until a late hour of the evening. A resolution was adopted recommending the publication of 5,000 copies of the president's address and an abstract of the proceedings of the meeting; several new names were added to the roll of membership; and a committee was appointed to report statistical facts regarding the results of the use and non-use of alcohol in the treatment of diseases at the next annual meeting of the Association.

All the officers were unanimously re-elected for the ensuing year, namely, for President, N. S. Davis, M. D., of Chicago, Ill.; Vice-Presidents, I. N. Quimby, M.D., Jersey City, N. J.; J. B. Whiting, M.D., Janesville, Wis.; F. E. Yoakum, M.D., Shreveport, La., and J. Taft, M.D., Cincinnati, Ohio. For Secretary, T. D. Crothers, M.D., Hartford, Conn. For Treasurer, G. W. Webster, M.D., Chicago, Ill.

The next annual meeting is to be held in Milwaukee, Wis., during the first week in June, 1893. The objects of this organization and the strictly scientific character of its work thus far, should command for it the earnest attention of the profession at large.

EDITORIAL NOTES.

The Health Boards of Cities.—Drs. Jacobi and Prudden, following the example of Dr. Janeway, have resigned their Health Board positions in New York City. In the editorial columns of the *Herald* of that city it is intimated that the Academy of Medicine will be called upon to pass its opinion on the existing methods of health administration, inclusive of *the practice of removing capable medical men from* office in order to make room for politicians. The writer adds regarding the retirement of Drs. Jacobi and Prudden: "These two physicians are eminent in their profession and their work in behalf of the public will be greatly missed. If it leads to any improvement in the methods, scope and independence of health officers, it would not be a bad thing." If it can be proved before the Academy of Medicine that competent medical men are removed on the pressure of office-seekers, the Academy should publicly and pungently criticise such action. And what is true of that body is likewise pertinent to similar representative organizations in other cities; the faithful medical official should to them be an object of pride and solicitude, who should not be left unsupported in the time of his attack and injury by malign influences of whatever nature.

Another Medical Dictionary Announced.—A new pronouncing dictionary of medicine, collated by Dr. J. M. Keating and H. Hamilton, is in preparation in Philadelphia, the birthplace of many lexicons. The publisher, W. B. Saunders, states that the types have been specially cast for the book, and the paper specially made; size royal octavo; price in cloth, $5. If we mistake not, each of the Philadelphia medical ok concerns has its new diction-director, while me of them have more than one to look after. ord-book making is in the ascendancy at the pres- t time, and not only are publishers ready to make eir ventures, but there is no evident lack of ready orkers in that most laborious of literary fields. rom a recent article in the *New Englander* we gain hint of explanation and a *raison d'etre*, when it tates that "we are living in a markedly linguistic ra, when more and better work is doing in the sphere f English philology than in any preceding era— ork accomplished, it is pleasing to state, mainly by nglish and American scholars. One of the most ronounced forms of this modern movement is lexi- ography. As the closing decade of the century is ntered, we find that this movement is wellnigh at ts maximum, so that both at home and in England, o English book is commanding more attention than he English dictionary, and we are living more than ver in an age of words." There can be little doubt hat the *Index Catalogue* of the Surgeon-General's Of- ice, and the *Index Medicus*, have been both an incentive nd an aid to the army of the lexicographers. Some f them only have the grace and gratitude to publicly dmit their debt. In England, the publishers of ord-books are in less active competition, The "Lex- con of Medical Terms" of the New Sydenham Soci- ty has now reached Part XVIII (Mit–Ne). Four ears more will be required to finish it. Inasmuch s Part I was issued in 1878, the disparity between he early and the late numbers will afford entertainment to the critics and others who have the time to o into a comparison.

CHLOROSIS TREATED BY STOMACH WASHING AND REASOTE.—According to the *University Medical Magazine*, not enough has been seen in this country of the use of stomach washing and creasote in chlorosis. Noting the prominence of symptoms of gastric derangement present in a large number of chlorotic cases, Pick has given, in the *Wiener Klinische Wochenschrift*, the suggestion that more reliance should be placed on those remedial measures which relieve the atonic or dilated condition of the stomach than on iron. In sixteen cases, he has practiced daily the washing out of the stomach; all of these recovered in three or four weeks, whereas, they had resisted treatment by iron for a month or more. In other cases in which stomach washing was not thought expedient, he had recourse to creasote, using the following formula:

℞. Creasote, 3 grs.
Sugar of milk, 8 grs.
M. Make four capsules.
Sig. One after each meal.

The advantage derived from creasote is in its power to control the fermentative changes to which these patients are liable.

HYSTERIA SYMPTOMATIC OF RENAL OR ABDOMINAL DISEASE.—Leopold has expressed the opinion that hysteria is not a functional neurosis, but is the symptom of a pathologico-anatomical lesion that should be sought for and found. This cause is not by any means always in the sexual organs. Among the non-sexual causes he gives a prominent place to floating kidney and atonic condition of the bowels and of the abdominal walls. The treatment for floating kidney should be by a suitable bandage and not by fixation by suture: in which plan he has the support of Schramm and von Bergmann. In those cases in which atony of bowels exists, relief is frequently obtained by small meals, six or eight daily, with restricted fluids, repose after eating, and external massage after meals.

VICHY WATER IMITATIONS.—President Carnot, of the French Republic, and the lessor company, now holding rights in the Vichy springs, are plaintiffs in a suit against a New York syphon-water dealer. The defendant has for years been engaged in the imitation or purported imitation of waters of a certain spring, called "Grand Grille" of Vichy; the plaintiffs now ask that an injunction be granted against future infringements, and damages on account of past imitations. be awarded. From this bill of complaint, it appears that the French nation is the true owner of the Vichy property, and President Carnot appears in the suit in his official capacity, as head of the French government. If the plaintiffs win in this suit, any use of the word Vichy, as descriptive of artificial waters made in this country, will be interdicted. The defense has thus far simply indicated an intention to dispute the complaint on technical grounds, such as the question of jurisdiction and the like.

ADULTERATION IN THE UNITED STATES.—A writer in the Philadelphia *Star* refers to the enormous quantities of materials that are sold in this country, the only known use of which is to dilute or adulterate our food articles, and says: "It is estimated that ninety millions dollars' worth of fraudulent food-products are annually disposed of, in these United States, either mixed with good articles or sold in place of them." This represents the extent of the theft perpetrated on the consumer by men who coin fortunes with "cheap" wares. Incidentally the products of the farmer are depreciated, so that the producer feels the steal along with the consumer.

OIL OF CLOVES AND THE MOSQUITO.—The *Indian Medical Record* has a statement by a native surgeon to the effect that the oil of cloves is abhorrent to the mosquito. It is his habit to pour three or four drops of this oil on his pillow on going to bed. The insects never trouble him after that. Those of his family and friends who have tried the experiment, report similar gratifying results. The oil of cloves has been recommended by some observers, as an external application to allay irritation from the bites of insects.

TYPHUS FEVER IN BRITISH CITIES.—From the local reports collated by the *Public Health*, it is learned that cases of typhus fever have occurred in the following cities: Carlisle, 12 cases; Dundee, 27 cases and Cork 11 cases. At Glasgow, London and Liverpool, cases have been reported, a certain proportion of which owe their origin to importation from Eastern Europe. At Carlisle, the epidemic is reported to be at an end in the *Lancet* for June 11.

Dr. Julian J. Chisholm of Baltimore, has had the degree of LL.D. conferred upon him by South Carolina College of Columbia, S. C.

Barnes Hospital and Medical College.—Robert A. Barnes, who recently died in St. Louis, bequeathed more than a million of dollars to endow a hospital and found a medical college. An organization of the institution is already effected, with Dr. Chas. H. Hughes as President of the faculty and member of the Board of Trustees.

In the last issue of The Journal, Dr. Truax directs attention to what he believed to be an inaccuracy in the official report of the late meeting at Detroit. The report was made by the most reliable and experienced medical society stenographer in this city, and our attention is directed to the fact that the report as published pertaining to the appointment of the committee referred to by Dr. Truax was correct, and so decided by the Association.

ABSTRACTS.

Decadence of Surgical Antisepsis in England.—In the *Northwestern Lancet*, the London letter repeats the assertion, that has been made elsewhere, that London surgeons have departed from their first love for antisepsis. The writer was surprised to see the instruments taken from their cases and then dipped in a perfunctory manner in the bath; after which they were used without further precaution. At the London Hospital, another visitor, a Frenchman, at the side of the writer, expressed some surprise, *but admitted that he* had been told that the English surgeons are no longer the strict observers of surgical cleanliness that they once were, and that Mr. Lister is the least cleanly of them all, in point of fact, the word "dirtiest" was the one employed by the French guest—a forcible expression to say the least.

A New Treatment of Acute Urethritis.—Drs. Cotes and Slater have contributed to the *Lancet* for February 27 some new points in the treatment of acute gonorrhœa. The patient is first of all told to empty his bladder, after which he reclines upon a couch. An endoscope tube, warmed and oiled, is then passed into the urethra. Ordinarily there is no great amount of pain produced by the passage of this instrument, but at times it may be sufficiently severe in sensitive persons to make it desirable to previously inject a 10 per cent. solution of cocaine. The urethra is then carefully cleansed by dry cotton wool, attached to a stilette, and examined with the aid of electrical illumination. The precise extent of the inflammation can be clearly seen. It is, as a rule, about five inches back of the meatus, or it may be four inches if seen as early as the third day. The implicated area is readily recognized by its swollen, bright-red appearance as contrasted with the rosy color of the uninflamed mucous membrane. It is expedient not to pass the endoscope far back of the posterior limit of the urethritis, which is usually quite sharply defined. Another cleansing is next done, so as to remove all of the discharge that can be brought away. A mop of cotton-wool wet with a solution of nitrate of silver, 10 grs. to the oz., is then passed completely through the tube and beyond it. The tube and mop are drawn out together. For the two inches nearest to the meatus a fresh mop is used, so as to thoroughly dose this very susceptible part. The pain caused by these procedures passes away in ten minutes. The patient is told to take a hot bath that night, and to remain in bed the following day. A saline purgative and an alkaline or balsamic remedy may be given internally. From four to six times daily the urethra should be injected with a simple cleansing injection.

Over forty cases treated in this way have averaged a cure in twelve days; chordee was present in a few of them. Th merits of this treatment seem to be, first, that the practitioner can see the tissues which he is about to medicate second, that the application is brought into contact with surface that has been thoroughly cleansed; and third, tha the application is made at a time when the walls of th urethra are stretched, so that its furrows and folds hav been obliterated. The proponents of the treatment regar the nitrate of silver application with especial favor, for the hold that it is not only a good microbicide, but exerts healing influence upon the diseased mucous membrane.

DOMESTIC CORRESPONDENCE.

Thyroid Dislocation of the Femur, with Integrity of the Ileo-femoral Ligament.

To the Editor of the Journal of the American Medical Association

Believing the following to be a rare, if not unique form of accident I am induced to report it:

On the morning of Nov. 20, 1891, Hugh Taylor, age 7, fell from the back of a mule. As no one saw the fall, it cannot be told how he struck the ground, but he was unable to arise on account of injury to the left hip.

I saw him two hours after the accident, and found him lying upon his back inclined to the left side. His left leg was flexed upon the thigh, and the thigh flexed upon the trunk to an acute angle, and abducted to such an extent as to rest easily upon the bed, in the position he had assumed, without any extra support. There was tension of the abductor muscles, on the inner side of the thigh. The hip was flattened. The limb was fixed so that I was not able to abduct or extend it.

Diagnosis.—Thyroid dislocation of femur, with integrity of the ileo-femoral ligament.

Having administered an anæsthetic, I placed him on his back with an assistant to steady the pelvis. Standing on his right side I grasped his thigh just above the knee with my left hand, and the left buttock with my right hand, the thumb being on the perineum. I then flexed the thigh strongly on the trunk and brought the knee across the middle line so as to throw the head of the bone, below and external to the acetabulum. Then carrying the limb upward with both hands, I attempted to reduce by extension; at the same time, as the ileo-femoral ligament was put on the stretch, rotating the limb slightly *outward* to relax the ligament and direct the head of the bone toward the socket. The first attempt failed but the second succeeded, and while in the act of rotating the limb, reduction was effected with a dull snap, audible only to myself and the nearest assistant. The limb dropped easily beside its fellow, and all the appearances were normal. Rapid and complete recovery followed.

T. B. Hill, M. D.

Ruff Creek, Pa.

THE VALUE OF MILK LABORATORIES FOR THE ADVANCEMENT OF OUR KNOWLEDGE OF ARTIFICIAL FEEDING.

BY T. M. ROTCH, M.D., OF BOSTON.

Two important factors are demanded by physicians of the present day in solving the problem of rational medicine: First, a means of saving time; second, exact methods of work.

I have long felt that the artificial feeding of infants should be reduced to a more exact system, and that in this way an endeavor should be made to rescue this important branch of pediatrics from the pretensions of proprietary foods and the hands of ignorant nurses. With this purpose in view, I have established a laboratory in which the materials used are clean, sterile, and exact in their percentages, and are combined in any proportion that the physician may wish to prescribe. Laboratories of this kind should be established everywhere, and physicians should write prescriptions for their infant patients' food and put them in the hands of the milk-modifier in his laboratory, just as they write for combinations of drugs in disease, and entrust them to the pharmacist in his drug shop. As the result of clinical experience in infant feeding, I have reached the conclusion that slight changes in the percentages of the three elements of milk of which we have most accurate knowledge, namely: the fat, sugar and albuminoids, have an important bearing upon the management of the digestion and nutrition of infants.

In analyses of milk from seven women the fat, sugar and albuminoids varied to a marked degree, and yet the infants all digested well and throve on their individual percentages, while what agreed with one produced serious symptoms in another. It seems, therefore, that so far as milk is counted upon as a food, it should be understood to be a general name of the food for the infant, just as dinner is a general name of food for the adult.

This general dinner (milk) of the infant, should also be modified in its various parts to suit the digestion of the individual infant.

Perhaps it would be of interest to know what materials were needed, and what processes were gone through with, in carrying out the prescription of the physician.

A laboratory such as that described has already been established in Boston, and is in successful operation, a number of physicians having found it to be an indispensable adjunct to their daily practice.

An important matter is the careful supervision of herds of cows especially selected as to breed and systematically fed, so that the analysis of their milk should be of an almost unvarying percentage. The morning's milk of these cows, milked into glass and kept scrupulously clean, is rapidly cooled and in a few hours delivered at the laboratory. The atmosphere of the laboratory is kept pure and fresh by means of a large fan that keeps up a constant outward current of air. The laboratory itself is lined with white tiles, and contains a separator by means of which a stable 16 per cent. cream can be quickly obtained from the milk. There is also a large sterilizer into which not only steam can be introduced, but in which the milk can be exposed to high or low temperatures, at the will of the modifier.

Having once obtained a pure, clean skimmed milk and cream of a stable percentage, it is merely a matter of mathematic calculation to combine these fluids in such proportions as to produce a mixture in the percentage of fats and albuminoids prescribed by the physician.

The sugar percentage is obtained in like manner by using a carefully prepared 20 per cent. solution of milk sugar and distilled water.

Diagrams were made to show the prescriptions written by the physicians in fat, sugar and albuminoid percentages, the same prescriptions translated into drachms and ounces by the milk-modifier, and the figures returned by the chemist to whom the modified milk was sent to test the accuracy of the modifier's calculations.

I have had a large number of test analyses made, so that there is no longer a doubt but that fairly exact combinations can be made in this way.

As the chemistry of the mineral matter in woman's milk is so little known, it is better to ignore that element for the present. Three figures only need be remembered, corresponding to the percentages of fat, sugar and albuminoids in average human milk—namely: 4, 7 and 1.50.

Starting with these figures, the physician can then easily change one or more of them, either to increase or decrease, according to the need of the especial infant.

As objection has been made to sterilizing at 212° F., this could just as well be done at the safer and lower temperature of 167° F. in the laboratory sterilizer.—*Medical News.*

NECROLOGY.

Dr. Herbert Fearn, of Brooklyn, died June 25, 1892, aged 58 years. He was born in England, but was brought to this country while a child. His medical education was obtained in New York City, at the now defunct college on Thirteenth street with which Carnochan, Peasly and Fordyce Barker were identified, graduating there in 1857. He was a member of numerous societies, accepting official responsibilities in a few of them. Among these were the Royal Arcanum and the Central Reform Association, a taxpayers' league for the repression of dishonesty in civic affairs. He read before the Kings County Medical Society, in 1871, a paper on the use of veratrum viride in large doses as a substitute for blood-letting in puerperal convulsions, which was probably an original proposition with him. Many physicians subsequently reported favorable results, and Dr. Fearn was led to believe that not a few lives of mothers, and infants as well, had been saved by an heroic dosage of veratrum. The cause of Dr. Fearn's death was fatty degeneration of the heart. He was an earnest, thoughtful and considerate man and was constantly employed upon the welfare of his fellows.

Death of an Eminent Medical Author.

The death of Sir William Aitken, of Netley, removes a pathologist and medical author of the first rank. The American profession were familiar with his merits, through his medical treatise, first issued in the sixties and which passed through seven or more editions in England and this country. He was for many years the professor of pathology at the Army College at Netly, and an examiner in medicine for various public services. He was a member of the Royal Society and was made a Knight in honor of the Queen's jubilee in 1887, and in recognition of his services to military medicine and sanitary science. In the latter field he had been a co-worker with the late Professor Parkes. His death took place on the 27th ult., at which time he was in his sixty-seventh year.

BOOK REVIEWS.

Proceedings of the Florida Medical Association. Session of 1891. Printed for the Association at Jacksonville, 1891.

This pamphlet of eighty pages gives a report of the annual meeting at Pensacola, held in April, 1891. The growth in the society is indicated by a three day convention fairly well attended and by contributions from numerous sources. The Association has had its importance increased by the workings of the Medical Examination legislation, and the address of the Presiden [illegible] Thomas P. Gary, of Ocala, shows the importance [illegible] izing to the utmost the protective properties accorded to the regular profession of Florida, under Examination Acts. That State, he says, is prospering, is growing in wealth and reputation; and from that very fact invites the attention of quacks and humbugs, against whose presence in the State the Medical Boards have been called into existence to protect the public. Dr. James C. Neal, of Lake City, contributes a paper on Legalized Crime in Florida, in which he refers to the ignorant practice of midwifery by the rural dame and black granny. As a result of extensive correspondence and his own observation, he thinks that at least fifty mothers and twice as many infants are annually lost through these ignorant persons. A list of forty cases is given to show the various repugnant practices that are indulged in, both as to the mothers and their offspring. Dr. Neal points out the need of a change in the laws governing this subject, so as to obliterate the quasi-protection that at present seems to forbid the prosecution of ignorant but homicidal midwifery. A long report on leprosy by Dr. R. P. Daniel is presented on behalf of the State Board of Health growing out of unproven statements, made through the press, that there were numbers of lepers at Key West and Tampa, engaged in the manufacture of cigars. The truth of the matter appears to have reduced the number of leprous persons down to six or eight at any one time; and of late years, through death, that number has been decreasing. These unfortunates are kept off the street, and no instance is known where the disease has been communicated to any other member of the family. The author believes that the Key West cases were imported from Havana, "a nursery of infection" that is dangerously near that part of our domain. The writer truthfully remarks that it is the duty of the State, and not of the town or county where these cases chance to become located, to make provision for leprosy. Louisiana has done its duty in this regard, and already has its hospital and thus cares for those who, through no fault of their own, become outcasts from society and the victims of a lingering, loathed malady. These lepers are sick people and not criminals; the spirit of our times and country forbids that they shall be injured by harsh treatment or by a studied neglect.

SELECTIONS.

HOT AIR REGISTERS IN FLOORS.—We have noticed on several occasions a most disgusting, if not dangerous, practice arising from placing hot air registers in floors. Reference is made to using the register for the purpose of a cuspidor. If attention is paid to this, one will be surprised to note the number of persons guilty of this act.

Recently in a hotel heated by natural gas, and having a large hot air register in the floor, we saw not less than half a dozen persons discharge their saliva into it. One of these was the proprietor of the hotel, an old man suffering from chronic bronchitis with a copious muco-purulent expectoration. One can scarcely imagine anything more horrible. And if we consider that consumptives may sometimes cast their expectoration into the register, the danger of the practice becomes apparent; for a more efficient method of scattering germs of tuberculosis through the air of an apartment could not be devised.

The floor is seldom or never the place for a hot air register. With the greatest possible care a considerable amount of dirt will collect in it, polluting the air more or less, that enters the room. In the absence of cuspidors, it always offers a tempting place for the chewers of tobacco to dispose of their spittle without betraying their filthy habit. Persons coming in from out of doors, with wet, dirty feet, will nearly always stand over the register to dry their shoes, affording another source of air pollution. Other objections present themselves, but those given should suffice to condemn placing hot air registers in floors, and especially in public places.—*Monthly Sanitary Record* (Ohio).

IT HAS been decided that the next Congress of Food Analysts shall take place in Vienna in 1894. A committee has been appointed to take steps for the preparation of "A Codex Alimentarius," in accordance with a resolution passed at the previous meeting of the Congress in 1891.

DISCRIMINATING AGAINST TWO-YEAR COLLEGES.—The Oregon State Board of Health has adopted a rule defining a medical institution in good standing to be one requiring three regular sessions of six months each, covering three years' time. A Dr. T. Barwood was rejected on the ground that the school from which he graduated does not have such a three years' course. He brought the case before the circuit court, which rendered a decision adverse to the power of the State board to make such distinction. On appeal to the supreme court the decision was overruled and the authority of the State board sustained.

THE TERM "REGULAR" DEFINED.—The Surgeon General of the United States rendered a decision last fall, which, coming from so high an authority, ought to satisfy the most exacting for a definition of the word "regular."

In the army regulations there is a paragraph which specifies concerning the qualification of the physician being admitted, and says he must be a graduate of a regular medical college. A member of Iowa Homœopathic Medical Society wrote a letter to the Surgeon General, asking him to state definitely what was meant by the word "regular."

The answer was as follows: "The term regular as used in paragraph 1544 Army Regulations, is used in its most comprehensive sense, as indicating a college well equipped and prepared to cover the whole ground of the science and art of medicine in its teachings, and requires not less than a three years' course of study to secure its diploma."

MISCELLANY.

THE MEDICO-LEGAL SOCIETY OF CHICAGO.—At the annual meeting held June 4, officers were re-elected as follows: President, Judge Oliver H. Horton; vice-presidents, Dr. Daniel R. Brower and Dr. James Burry; treasurer, Dr. Joseph Matteson; secretary, Dr. Archibald Church.

OFFICIAL LIST OF CHANGES in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from June 25, 1892, to July 1, 1892.

Capt. William O. Owen, Jr., Asst. Surgeon U. S. A., is granted leave of absence for one month, with permission to apply for an extension of one month.

First Lieut. Frank T. Meriwether, Asst. Surgeon U. S. A., now on duty at Ft. Adams, R. I., will report in person to the commanding officer, Madison Bks., N. Y., for temporary duty at that post, during the absence of Capt. Henry S. Turrill, Asst. Surgeon U. S. A.

First Lieut. Charles F. Mason, Asst. Surgeon U. S. A., on being relieved by Capt. Raymond, will report in person to the commanding officer, Ft. Snelling, Minn., for duty at that post.

Capt. Edward Everts, Asst. Surgeon U. S. A., is relieved from duty at David's Island, N. Y., and will report in person to the commanding officer, Ft. Robinson, Neb., for duty at that post relieving Capt. Henry I. Raymond, Asst. Surgeon U. S. A. Capt. Raymond, on being relieved by Capt. Everts, will report in person to the commanding officer, Ft. Washakie, Wyo., for duty at that post, relieving First Lieut. Charles F. Mason, Asst. Surgeon U. S. A.

First Lieut. Champe C. McCulloch, Jr., Asst. Surgeon U. S. A., now on duty at Ft. Sam Houston, Texas, will report in person to the commanding officer, Ft. Hancock, Texas, on July 1, 1892, for temporary duty at that post. By direction of the Secretary of War.

First Lieut. Henry C. Fisher, Asst. Surgeon (Ft. Yates, N. D.), is granted leave of absence for twenty days.

OFFICIAL LIST OF CHANGES in the Medical Corps of the U. S. Navy, for the Week Ending July 2, 1892.

Asst. Surgeon C. P. Baggs, ordered to Naval Hospital, Mare Island, Cal.

Surgeon M. C. Drennan, from Naval Academy and to Navy Yard, Norfolk, Va.

Surgeon G. F. Winslow, from Navy Yard, Norfolk, Va., and wait orders.

Asst. Surgeon C. F. Stokes, from Naval Hospital, Mare Island, Cal., and wait orders.

Asst. Surgeon G. A. Lung, from Naval Hospital, New York, and to U. S. S. "*Minnesota.*"

Asst. Surgeon G. H. Barber, from U. S. S. "Minnesota," and to Naval Hospital, New York.

P. A. Surgeon V. C. B. Means, from Navy Yard, New York, and to Naval Hospital, Norfolk, Va.

P. A. Surgeon N. H. Drake, from Naval Hospital, Chelsea, Mass., and to Navy Yard, New York.

Asst. Surgeon J. E. Page, from receiving ship "Independence," and to the U. S. S "Thetis."

ORIGINAL ARTICLES.

THE INFLUENCE OF PARTURIENT LESIONS OF THE UTERUS AND VAGINA, IN THE CAUSATION OF PUERPERAL INSANITY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY GEORGE H. ROHE, M.D.,

PROFESSOR OF MATERIA MEDICA, HYGIENE AND MENTAL DISEASES IN THE COLLEGE OF PHYSICIANS AND SURGEONS, BALTIMORE; SUPERINTENDENT OF THE MARYLAND HOSPITAL FOR THE INSANE, CATONSVILLE, MD.

I venture to report the following cases as a contribution to the etiology and treatment of puerperal insanity:

Case 1.—Mrs. A. T. White, aged 33 years, has been twice married, first at the age of 17 years. Of this marriage one child was born. Her husband died two and a half years after, and after remaining a widow four and a half years she married her present husband, who is a minister. There is no family history of insanity. In 1882, three days after the birth of her second child she had an attack of puerperal insanity, maniacal in character, which lasted five months. She remained well until October, 1886, and was then again attacked with acute mania. After this had continued ten weeks she was admitted to the Maryland Hospital for the Insane. She was very much excited, violent toward her husband and others with whom she came in contact. She was extremely profane and obscene, irritable, morose and disposed to fight on the least provocation. She soiled her clothing, bed and room and was a source of great trouble to the attendants. A pleasant "good morning" addressed to her by the physician on passing through the ward was generally the signal for a volley of obscenity and profanity. She sometimes acted as if she had hallucinations of hearing, but on account of her ill-temper, no clear history of hallucinations or delusions could be obtained. She did not improve, but showed a progressive tendency toward dementia. Her menstrual periods were attended by an exacerbation of symptoms. She was always more violent at her periods. An examination was made of the pelvic organs last September, and the following conditions found to exist: The perineum was torn down to the sphincter ani, causing the vulvar opening to gape widely. The cervix uteri was lacerated to the vaginal insertion on the left side and to a slighter degree on the right. There was decided intra-pelvic induration on the side of the uterus. Believing that these abnormal conditions, together with the evident unfavorable influence of the menstrual periods, justified the induction of the menopause, I removed the uterine appendages on October 6, 1891. The operation was performed under aseptic conditions, all instruments and dressings being sterilized by steam and hot distilled water used both for cleansing the hands, surface of the patient's body and irrigation of the abdominal cavity. No chemical antiseptics or disinfectants were used. No drainage.

The right ovary was cystic and firmly adherent in Douglas' cul de sac. Left tube tortuous, and broad ligament thickened and congested. The abdominal cavity was irrigated until the water returned clear. Five deep and two superficial silk-worm gut sutures were employed to close the incision. Anæsthetic used, A. C. E. mixture. Patient recovered from the operation. Sutures were all removed on the seventh day and the wound found firmly united.

Two months after the operation, the patient had shown considerable mental improvement. She began to take an interest in books, pictures, flowers, etc. While her attempts at conversation were disconnected she dwelt more on pleasant themes, and her former violence of speech had almost entirely left her. After Christmas she began writing letters to her husband, making inquiries of her children and expressing much affection for them. This she had not done for over five years. She continued to improve, up to a certain point, and at her husband's visits, she received him affectionately, but quietly. While memory of past events and love for her husband and children seemed to return gradually, there was still a lack of coördination of thought, and this has not further improved. The brain disorganization (physical basis of dementia) had probably progressed too far to be restored even approximately to the normal. At the time of writing, eight months after the removal of the appendages the patient is quiet and cheerful, although relapsing into profanity when irritated. She no longer fights, or soils her bedding, room or clothing. She dresses and undresses herself, makes her bed, sweeps her room and waters the flowers and plants on the ward. She is not restored mentally, probably never will be; indeed, is likely, I think, to pass deeper into dementia. But, from a violent, excited, noisy and dirty patient, she has improved so much as to allow her to be kept on the quietest ward in the hospital, and this gain may, I think, be largely, if not entirely ascribed to the removal of the uterine appendages. I may say that I subsequently sewed up the lacerated cervix and restored the vaginal outlet by Emmett's procedure, without any appreciable effect upon the patient's mental condition.

Case 2.—Caroline A., white, aged 39 years, married fifteen years and the mother of seven children. Last child was born in April, 1887, four months before her admission to the hospital. No history of insanity in the family. Four weeks after the birth of her last child she suddenly developed delusions of persecution; claimed that some one was after her and trying to kill her. Her language became very profane and vulgar. She at one time made a violent attack upon her mother. She was one of the most troublesome and destructive patients in the hospital. She would strip herself on the ward, attack the attendants and the other patients, use the most obscene language, break the furniture, dig the plaster out of the wall of her room, soil her clothes, bed and room, jump at and hug any man coming within her reach and make herself generally disagreeable to her surroundings. She was always worse during her menstrual periods, and at these times was kept secluded in her room on account of her tendency to strip herself.

Vaginal examination showed a moderate perineal tear, but a deep bilateral laceration with eversion and erosion of the cervix, and enlarged uterus. Pelvic induration of moderate degree in Douglas' cul de sac. Abdominal section and removal of the uterine appendages was done on December 15, 1891. Tubes on both sides were thickened, congested and convoluted. Left ovary adherent. Small cyst in left broad ligament. No irrigation. No drainage. Patient recovered well from operation and sutures removed on the seventh day. Incision firmly united.

The patient seems to be slowly recovering a part of her mental faculties. She has become cleanly in habits and no longer indulges in her former vulgarity. The day before this present writing, she received a visit from one of her daughters and her youngest child and received them with every demonstration of affection. Her conversation is not connected, but it is now neither violent nor offensive. She sleeps in a dormitory with six other patients, eats in the ward dining room, keeps herself neat and clean, and is industrious in the use of the needle. Barring the non-restoration of her mental faculties, there has been a complete transformation in the habits, acts and speech of this patient.

Case 3.—Mary L. B., age 37 years, white, married thirteen years, and mother of six children, the youngest four months old at the time of her admission to the hospital. The family history is bad, mother being at one time insane, and her father very intemperate. She was admitted to the hospital May 16, 1890. She had one previous attack of insanity ten years before the *present attack, but it is not certain whether* it was connected with the birth of any of her children. She had delusions and hallucinations. She was never very violent, but was talkative, exalted, and would strip herself on the ward. She was very much run down when brought to the hospital, and gained strength very slowly under stimulants and nutritious diet.

During her menstrual periods she became exalted and evidently had increase of sexual excitement. Her face was *flushed and she would try to get near to, and touch the* physician passing through the ward. At other times she was quiet and unobtrusive, but evidently *under the influence* of her delusions.

Examination disclosed bilateral laceration of the cervix with thickening of the posterior lip. There was an inflammatory induration on the left side of the uterus, which was very sensitive to pressure.

On November 25, 1891, the uterine appendages were removed. *Left ovary* adherent and tube thickened and convoluted. Irrigation. No drainage.

Patient recovered *without* a bad symptom. *Stitches* removed on the seventh day, and incision found firmly united.

In this patient delusions of personality continued for several weeks after the operation. but gradually faded away. Her conversation became connected and rational and in two months after the operation her mental faculties seemed to be completely restored.

Her climacteric symptoms, headache, backache, constipation and nervousness, were especially severe, but at this writing, over six months after the operation, their severity is lessened, and she is more comfortable. Her mental condition is completely restored to the normal, and as soon as the symptoms of *the menopause above mentioned disappear,* I shall discharge her from the hospital as recovered.

Case 4.—Mrs. Fannie L. C., aged 28, white, married and mother of three children. No hereditary history of insanity. Eight days after the birth of her first child she became insane, the mental disturbance lasting two weeks. Seven months after the birth of her second child she had another attack which lasted fifteen weeks. A third attack began a year after the birth of her last child. Three days after this outbreak (on December 28, 1891) she was admitted to the Maryland Hospital for the Insane. She was excited, but very weak. *Her language was shocking in its profanity* and obscenity. Sexual excitement was pronounced. For several weeks her pulse was so weak *and rapid, that at times* her life was despaired of. She was kept in bed and fed every two hours with milk, eggs and brandy. Digitalis was given to keep up the force of the heart. Her mental condition did not show any signs of improvement with returning strength. An examination under anæsthesia disclosed a deeply ruptured perineum with gaping vaginal entrance, lacerated cervix and prolapse of the right ovary.

On March 9, 1892, the uterine appendages were removed. *No adhesions were found.* Both ovaries were very much enlarged, being at least three times the normal size.

On the day previous to the operation, this patient was cross, profane and obscene in [illegible] Within two hours after the operation, as I [illegible] she burst into tears, asked me to forgive her for the ugly language she had used toward me and the assistant physicians and attendants, and acted *in an entirely rational manner.* She recovered well from the effects of the operation, but on the *eighth day after the operation,* and the day after removal of the sutures, the evening temperature ran up to 102.4°, and on examination a mural abscess was discovered, which discharged freely through the stitch holes for about two weeks. In spite of this, however, her progress toward recovery, both physical and mental, was uninterrupted, and she was discharged, well, on May 8, two months after the operation.

It will be noted that in each of these cases there was some lesion of the genital passage dating from parturition. In three out of the four cases there was likewise inflammatory adhesion and other morbid changes in the ovaries and tubes. In the fourth case there was great enlargement of the ovaries, with prolapse of one of these organs, subjecting it to more or less constant irritation.

Do not these cases force us to the conclusion that the etiology of puerperal insanity is to be sought, not in the brain itself but in pathological conditions of the sexual organs—conditions which, in the first place, favor the absorption of septic materials, and which, secondarily, leave behind them a source of irritation, to which such sensitive organs as the ovaries cannot be constantly subjected without deleterious effects upon the organism.

I point with some satisfaction to the results ob*tained from the radical treatment* adopted. Out of four cases, two are entirely recovered. The other two were cases already subjects of brain enfeeblement, in whom no recovery could be hoped for, much less expected. However, the transformation of these women from dirty, noisy, destructive and obscene viragoes to persons who can be tolerated upon the quietest ward of the hospital is a distinct gain to the institution and unquestionably to the patients themselves. In cases such as these, I am sure no objection based upon the "unsexing" of the patients can hold. My experience inclines me to the opinion that there are other reasons besides a pathological condition of the pelvic organs, justifying the removal of the ovaries and tubes in insane women, but when there is actual local disease demanding the operation without regard to the mental condition, a physician having the good of his patient at heart, dare not hesitate.

Time is lacking to review here the unsatisfactory [illegible] that have been propounded to account for the origin of *puerperal* insanity. I *offer* here no theory, but submit the cases which I believe justify the following conclusions:

1. Puerperal insanity is, in at least the large majority of cases, an infection psychosis.
2. Without rejecting the influence of other factors such as heredity, anæmia, exhaustion, mental shock and distress, careful observation will show that few cases of puerperal insanity occur without preceding *or coincident puerperal infection.*

The reasons for this opinion may be briefly summed up as follows:

1. Puerperal insanity occurs in the great majority of cases within the first ten days after delivery—about one-half in the first five days—the same period during which puerperal infection usually occurs.
2. It is usually accompanied by elevation of temperature and other evidences of febrile disturbance.
3. The clinical form in which puerperal insanity manifests itself is, in the majority of cases, that of acute, delirious, or confusional mania. Depressive states are rare except as secondary forms. In other words, the most frequent condition is one most closely resembling febrile delirium.
4. The death-rate is much higher than in simple mania. Death occurs from exhaustion, usually with high temperature and rapid pulse.
5. *Post-mortem examinations,* though *apparently* infrequent in these cases, have shown grave involvement of the pelvic viscera.
6. Examinations of the pelvic organs during life show lacerations of the perineum and cervix uteri (facile channels of infection in the puerperal woman). As secondary conditions are found intra-pelvic (peritoneal) inflammations, and consequent abnormal locations, fixations and congestions of the uterus, tubes and ovaries.
7. The results of operations seem to show that removal of local sources of irritation increases the chances of recovery from the mental disease.

PUERPERAL HYSTERIA (INSANITY?).

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY W. P. MANTON, M.D.,
OF DETROIT, MICH.
Vice-President Medical Board of the Woman's Hospital and Foundlings' Home; Consulting Gynecologist to the Eastern and Northern Michigan Asylums for the Insane, and St. Joseph's Retreat; Lecturer on Obstetrics, Detroit College of Medicine, etc.

While the alienist, the surgeon and the gynecologist have long recognized the importance of hysteria in its counterfeit presentments of various morbid conditions of the human body, the obstetrician has been exceedingly backward in connecting neuromimetic phenomena with the disorders incident to pregnancy and the lying-in state.

Indeed, a careful review of obstetrical literature for the past few years, fails to discover more than a half dozen or so articles in which this important subject has been at all considered, while the text-books on midwifery contain little or nothing upon this point, and nowhere have I been able to find a word written in regard to hysterical mental conditions developing during labor or the puerperium. Yet I am quite sure that manifestations of this nature cannot be so very infrequently met with, the fact probably being that they are not recognized as such, but are put down as simple cases of puerperal mania. It seems to be the general impression that the insanity of childbed is a mental disorder peculiar to lying-in women, differing essentially in its manifestations from insanity developing under other conditions.

The careful observation of a considerable number of such cases, and the study of their histories as noted in asylum case books, convinces me that this is not so, and I do not believe that even the most expert alienist could, without a previous knowledge of the case, point out a single patient suffering from this disorder from a ward full of insane women non-puerperal.

The fact that a patient becomes mentally sick during the act of parturition or later, does not go to prove that the form of psychoses from which she suffers differs in any respect from mental derangement appearing at other times.

The classification of such cases into melancholia, mania and, rarely, katonia, is, it seems to me, more or less arbitrary and incorrect, since few cases, excepting, perhaps, the very acute septic manias which speedily terminate fatally, but display sooner or later, and generally repeatedly, both of the two first mentioned symptoms. The psychic manifestations, therefore, during the course of the disease, should be recognized and spoken of only as symptoms, not forms, of the brain disorder. It is not my purpose, however, to dwell upon this somewhat mooted question. In the present communication I simply desire to call attention to a symptom of insanity, a condition which might be termed a functional psychosis, and not generally recognized. Patients afflicted with this hysterical psychosis, invariably present a history of ante-partum hysteria. The attack develops suddenly either during labor or soon after, continues for a few days, generally less than a week, and as suddenly disappears, leaving the intellect clear and unimpaired.

During the whole period of the attack the bodily functions continue normal, the lochia are not diminished, and there is, as a rule, no fever.

The transition from sanity to insanity, and the recovery from the mental derangement, is generally so abrupt that the symptoms appear and disappear, to adopt the language of Levingstein-Schlegel, "as by a blow."

It has been my fortune to observe several of these cases, one of them about two years ago at the Detroit Woman's Hospital, and another more recently, the only one of which I have adequate notes, in my private practice. The history of this case will illustrate the point which I desire to make:

Mrs. S., a large, robust-looking woman of 24, passed through her first pregnancy without particular disturbance, excepting that at times she was nervous and mildly hysterical—a condition which had existed for some years—and also suffered from obstinate constipation. As far as I have been able to learn, the family history is good. A married sister is said to have been flighty after the birth of her child.

September 2, at 4:20 A.M., I delivered the patient with forceps of an 8-lb. girl. The labor had been comparatively easy, but toward the end of the second stage, the pains diminished in frequency and force, and finally became so feeble as to necessitate the use of instruments, just as the head had reached the perineum.

As is my custom, the patient was given a small amount of chloroform to inhale during the pains of the second stage, and complete anæsthesia was induced for a moment when the forceps were applied and the head delivered.

There was a slight tear of the perineum beyond the fourchette, but not sufficient to necessitate suturing. The blood loss was slight.

The patient came out of the anæsthetic well, was bright and cheerful, suffered no pain, and expressed her gratification that the trying ordeal was safely passed. I left her at 7:30 A.M., quiet and comfortable.

At 8 o'clock, half an hour later, her husband, who had been out of the city, and whose absence during the labor had been a source of worry to the patient, returned, but she failed to recognize either him or, for the first time, her mother and the nurse, both of whom had been present with her from the onset of labor. She also quickly developed hallucinations of sight, became voluble and incoherent in her language, talked of a crowd of people about her and of boats, complained of pain in the back of the neck—over which she held her hand, and asked to have her husband brought to her although he was then standing within a few feet of the bed. During the day she slept at intervals, was quiet, pleasant and obedient, and took her nourishment without objection. The pulse was 87, the temperature 98.4. The lochial discharge was normal, and uterine and abdominal tenderness absolutely wanting. The catheter was used three times during the day on account of slight tumefaction of the parts, with probably, voluntary retention of the urine.

September 3. Had a good night. Condition much the same as yesterday. When her baby is brought to her she looks at it with interest and then turns away. Asked if she is not pleased with her child she smiles and observes that "it jumps." Pulse and temperature normal.

September 4. Slept well last night. Hallucinations less marked. Recognizes the doctor, and calls him the "man", but cannot recollect his name. Asks him to come back soon and to bring her husband with him. Bodily condition normal; voluntary micturition.

September 5. Mental condition somewhat improved, although the hallucinations remain and she is still incoherent. Says that she feels sore all over. The pain in the back of the neck still continues but is evidently less severe. When asked a question which she does not desire to answer she laughs and says "huh". Pulse, temperature and excretions normal; no abdominal tenderness. She is much pleased with a bouquet which her husband brought her, fondles the flowers and places them on her bosom, although she still persists in refusing to recognize the giver.

September 6. Slept well. The urine which has been plentiful, is now passed voluntarily and in considerable quantities. During the forenoon the mental symptoms continued as before, but at 6 P.M., while her husband was sitting by the bedside, her mind suddenly cleared, the hallucinations vanished not to return and she appeared as strong and well mentally, as she had been and was physically. She had, apparently, no memory of what had occurred since the labor. The nape ache had disappeared, and only a slight pain in the sacral region was complained of. From this time on the case progressed favorably and there was no return of the mental trouble.

Remarks.—In spite of the fact that so distinguished an observer as Levingstein-Schlegel, is of the opinion that a psychosis with hallucinations developing during the first weeks of the puerperium, in the absence of other (non-puerperal) infectious disease and without preceding eclampsia, is due to puerperal infection, even though a careful physical examination fails to demonstrate the presence of fever or other somatic symptom, I think that septic infection may be ruled out in this case. The only other condition with which the mental manifestation exhibited in Mrs. S's case should be confounded is that known as Transitory Frenzy (Transitory Mania, T. Melancholia), but as the history of the case shows a marked difference in the symptoms displayed from those seen in the latter condition, I think that I am quite justified in excluding this and ascribing the psychic disturbance to hysteria.

The reason why this condition is not mentioned in works on mental diseases, is because it never comes under the observation of the alienist, being of short duration, and always cared for at home by the family physician, who, in all probability, also fails to recognize the nature of the mental sickness.

83 Lafayette Avenue.

DISEASED UTERINE APPENDAGES AS FACTORS IN MUSCULAR AND JOINT AFFECTIONS.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual meeting of the American Medical Association, held at Detroit, June, 1892.

BY M. B. WARD, A.M., M.D.,

Professor of Gynecology Kansas Medical College, Fellow of the American Association of Obstetricians and Gynecologists, President of the Western Association of Obstetricians and Gynecologists, etc.

Serious neurotic affections are so commonly attributable to diseased uterine adnexa, it is quite natural and, indeed, altogether the "latest style" to make diseased pelvic organs responsible for all morbific conditions when the true etiology is in the least obscure.

There is, perhaps, too much stress placed on the uterus and attached organs as the cause of systemic disturbances, and yet, it is frequently demonstrable that disease of these organs is the prime factor, or active agent in causing functional derangements oftentimes quite remote from the pelvis. In order that specialists shall not become too narrow in their views, it is prudent to endeavor to find the cause of nervous affections in every other part of the human economy, before any thought of the pelvic organs is considered. That is, should the patient give a clear history of suffering from disease of the pelvic organs, we should inspect with care every probable causative factor, before deciding that the entire fault is connected with the uterus or its attachments.

All are now agreed on one point, namely: that certain diseased conditions of the uterus and appendages will cause neuroses so grave in character that life is often endangered. This fact being established, general practitioners as well as specialists, should be considered extremely careless if they overlook, or fail to familiarize themselves with the histories of disturbances due to diseases of these organs.

Muscular contractions, and apparent joint affections due to para-uterine disease, especially adhesions which bind the ovaries and tubes against the pelvic fascia, are, perhaps, more common than we are accustomed to recognize. So far as my study of current literature has extended, I have failed to find anything definite regarding this factor of nervous phenomena.

Perhaps there is no special occasion to invite discussion of this phase of the subject, for it may have been mistaken diagnoses in the cases where muscular contraction of a permanent character, and apparent joint affections, have been recognized by the writer as due to pelvic disease.

The histories of the two cases which have been observed in my practice will, no doubt, enable the members of the Section on gynecology to better understand the claims of the author, than would dogmatic statements.

Mrs. F., aged 28 years, mother of two children; bed ridden for nearly one year; reduced to skin and bones; pulse 120 to 140.

Examination revealed a fixed uterus, and pelvis filled with a mass which suggested the condition of congealed wax.

The patient suffered greatly from examination. The left leg was flexed, *and immovably fixed. The left hip joint was* very tender to the touch and the patient presented every symptom of hip-joint disease. *After making my examina*tion, I was certain that the joint was free from disease. An operation to remove the diseased appendages and break up the adhesions was recommended only after stating that the prospects of recovery were doubtful and the patient might *succumb before an operation could be completed. There* was *no thought on my part that the muscular and joint* complication would be especially benefited by any operation in the pelvis.

The ovaries were buried *in the* pelvic fascia, and in removing them *there* was *much hæmorrhage.*

The inflammation had been so extensive that the ovaries, tubes and broad ligament were matted together as if they had been subjected to a white heat years before, which left them *without definite form. The uterine attachment of the* right tube was separated *in the scooping* process, *and there*fore, no ligating was done on this side.

The patient made a very slow and unsatisfactory convalescence, but within one year after the operation she had sufficiently recovered to do light house work, and the muscular and joint troubles were entirely absent.

The limb at the time of the operation was so firmly flexed that it was quite impossible to extend it *with the patient* anæsthetized, and we had to operate with the knee almost in our faces.

Case second was a girl 23 years of age, who consulted me for rheumatism, and partial paralysis of the muscles of back and lower limbs. For three years she had been gradually losing the use of her limbs and back, so that for the past year, she had not been able to walk without the use of one *crutch and a cane, or two canes.*

She could not turn in bed without first raising her body, and turning by the aid of her elbows. She could not lift her feet from the floor. She was a *constant sufferer.* She could not lie on her back on account of pain, and when she would turn on either side, there would be a dragging sensation which was anything but pleasant.

She gave a history of gonorrhœal infection contracted about four years ago. There were *symptoms of syphilis, but* no direct history, and after I had seen her a few times concluded that she had only been affected by gonorrhœa. She had been under the care of a large number of physicians, and treated for a number of diseases, among others hip-joint disease.

The limbs would sometimes become flexed, and she could not endure the suffering caused by forcing them straight. I watched *the case with much anxiety for a few weeks* before I could satisfy myself as to the cause of her deplorable *condition.* I examined her and could not find any masses in the pelvis, but there were strong adhesions of the uterus. She was tender but did not suffer greatly from the examination.

After I had examined her the third time I was almost certain that there were diseased and adherent ovaries causing all her trouble, and recommended an operation. The girl cried with joy when I informed her that an operation gave promise of great relief and perhaps permanent cure.

She wished it done immediately. I operated Oct. 31, 1891. The case was thoroughly explained before the operation, and Drs. Rogers and Sheldon examined the condition of the appendages after the incision was made. The left ovary was buried in the pelvic fascia so that it could hardly be felt, and in removing it the under surface was riddled. The tube was still patulous, and not adherent to ovary.

The entire trouble seemed to be confined to the left ovary. I removed the left appendage close to the uterus. The right side was slightly adherent, but not diseased, and after breaking up the adhesions it was allowed to remain. The patient experienced no pain, and was anxious to get up in twenty-four hours.

In one week after the operation she could turn in bed as quickly as any one, and in less than four weeks she went home, walking out of the hospital without the use of a crutch or cane.

In fact she never saw either crutch or cane after she got to the hospital. The patient works around the house from morning till night, and has been on the streets making calls.

She is as nearly a transformed person as one could wish. This young lady was married the first day of this month (June).

I know of only a few cases on record where the large joints were rendered almost useless, with partial paralysis of the muscles of the back and limbs, the result of ovarian disease and impingement. One of the latest writers on pathology of ovarian disease merely mentions the fact without giving any explanation.

In February last I did an operation on a lady 35 years of age for the removal of the diseased appendages, who had serious rheumatic trouble and an apparent shortening of one limb, with tender hip and knee joints on that side, and improvement took place at once, and has continued, but sufficient time has not elapsed to report the case as cured.

If this brief paper should provoke thorough discussion of this subject or feature of pelvic complications, the writer will be entirely satisfied.

THE INFLUENCE OF DELAYED AND INCOMPLETE OPERATIONS UPON RESULTS IN PELVIC SURGERY.

Read in the Section of Obstetrics and Diseases of Women, at the Forty-third Annual meeting of the American Medical Association, held at Detroit, June, 1892.

BY L. S. McMURTRY, M.D.,

OF LOUISVILLE, KY.

The development of pelvic surgery is of such recent period that it has been necessary to revise and alter year by year and month by month many of its principles, and to constantly modify and improve its practical methods. A few years back there was but one operation practically known to pelvic surgery, viz.: ovariotomy. In a brief period it has grown and culminated in a brilliant and important branch of the healing art. This has been accomplished by the earnest and devoted labors of a few men, who have extended its scope, perfected its methods, and placed it upon the firm basis of scientific accuracy and practical demonstration. That this great work has been accomplished by a few persistent laborers is well known; that from the very nature of things it must remain a distinct specialty is incontrovertible.

It is doubtful if any special branch of surgical practice was ever subjected to such a severe ordeal of criticism as has been the new surgery of the pelvic organs. The older ovariotomists met with fierce denunciations constantly, and ofttimes were persecuted by their professional colleagues. The new surgery has been criticised with serious severity, and has been made the target for ridicule as well. Now, fortunately, its days of probation are completed, and it is firmly fixed in its position as perhaps the most brilliant and efficient department of surgical practice. The history of pelvic surgery during the past few years is in many respects anomalous. Attracted by the brilliant results of the few, it was eagerly seized upon by many untutored in the pathology of the pelvic organs, untrained in diagnostic resources, and unfamiliar with operative methods. That the aggregate of results should be disastrous under such circumstances is not strange. The anomalous feature of the situation is in the fact that those who misapply the principles of this new branch of surgery have been the most severe critics of the few who, laying aside all other work, strove to perfect its methods, and elevate it to a standard of safety and accuracy. In the evolution of no other special branch of surgical practice has such a rigid standard been established as the statistical method to which the results of pelvic surgery have been subjected. It may be fairly claimed now that the test has been made, and the decision rendered by the discriminating judgment of the profession. To maintain the present proud position of pelvic surgery and to elevate its standard of efficiency, it is absolutely necessary that certain advantages be utilized in the light of advancing knowledge and established facts, to perfect methods and thereby improve results. It is in view of the circumstances I have recited that this paper is undertaken, to show how the results of established operations for pelvic diseases may be disastrously affected by delayed and incomplete operations.

Inflammatory diseases of the uterine appendages compose the largest class of affections of the pelvic organs requiring surgical interference. In the early stages of the inflammatory process, palliative treatment, consisting in rest, depletion with saline purgatives, and local use of moist heat, may beget cure by resolution. When such a favorable termination is unattainable, when recurring attacks of peritonitis have begotten fixation and retention with irreparable lesions of ovaries and tubes, operation by abdominal section is the only rational means of restoration. Before the inflammatory mass has broken down in suppuration; before perforation of bowel or bladder, or rupture into the general peritoneum, have obtained, enucleation and removal are comparatively easy and safe. When treatment by palliative methods even after pus has formed is persisted in, or temporary safety is secured by puncture through the vaginal vault, every day of delay complicates and increases the difficulties of the operation for a radical cure, and also adds to the dangers of the operation. It is moreover an established pathological fact, supported by abundant clinical testimony, that secondary lesions of the kidneys and lungs often follow from prolonged suppurative changes in the uterine appendages. The depuration of the blood often hinders convalescence after successful operation, and the opium habit so frequently associated with pelvic inflammations may remain as a miserable legacy to the long-suffering patient. Intestinal complications are the most common and serious difficulties encountered in operations for inflammatory diseases of the appendages. Unless the operator is prepared to deal skilfully with a torn intestine or wounded bladder, he assumes *unwarranted* responsibility in undertaking neglected cases, for he will frequently determine the fate of patients by the manner in which he repairs these lesions. All this could be averted, dangers and complications reduced to a minimum, the patients spared prolonged suffering, and the results of treatment made complete with increased safety, by prompt resort to operation. Moreover I will endeavor to show, in the course of this paper, that delayed operations upon the inflamed appendages are very frequently incomplete, and hence are disastrous, either ending fatally at once or after prolongation of the disease.

Fibroid tumors of the uterus, or more properly, myomata of the uterus, constitute another form of intra-pelvic disease in which the disastrous results of delay are conspicuous. These tumors were formerly considered very innocent, and by many practitioners they are now treated as of trivial import. The soft myoma, prone to cystic degeneration, œdema and suppuration, is one of the most formidable and deadly conditions with which the pelvic surgeon has to deal. These tumors are almost invariably associated with disease of the Fallopian tubes and ovaries. In my latest experience with an uterine myoma, three weeks since, the rupture of the Fallopian tube on the right side flooded the entire pelvis with pus. This is not an unusual complication. Fibroid tumors produce persistent uterine hæmorrhage by which the patient is exhausted as with profound anæmia. When submitted to operation otherwise safe, these cases are often lost from the extreme anæmia which has obtained. In the early stage of these growths, before the appendages are carried behind the tumors or incorporated in the mass, the removal of the uterine appendages is a safe and efficient operation. The mortality of this operation in skilled hands is very small. It arrests hæmorrhage and, as a rule, arrests the growth of the tumor. In my own work this operation has been among the most satisfactory in its immediate and remote results. It is in connection with a consideration of this operation that Mr. Lawson Tait exclaims: "The whole of my experience in every department of abdominal surgery is one continuous outcry against delay."

Since we have learned more of the complications and possibilities of fibroid tumors of the uterus, it is known that in a considerable proportion of cases the tumor not only does not cease to grow at the menopause, but in *fact grows more rapidly after that* period. As Skene states, "*the organic forces* which maintained the menstrual function being no longer called for, are devoted to the growth of the myoma." I have done abdominal hysterectomy in one instance in which the tumor took on its most active growth after the menopause, and when the patient was in her fiftieth year the tumor had risen to the diaphragm almost. With profound anæmia, interference by pressure with the digestive functions and circulation, irritation of bladder and rectum, the patient is ill prepared to withstand any serious operative procedure. In recognition of these facts, Price, whose experience with these tumors is the largest and whose results are the best, has made a plea for early hysterectomy as did Bantock for early ovariotomy. When his plea shall have been adopted, we will witness the same improved results as obtained in response to Bantock's plea for early ovariotomy.

It would seem that the necessity for prompt resort to operation in cases of ruptured tubal pregnancy would need no argument or emphasis, in view of the deadly nature of the lesions involved. Yet we hear from time to time of a conservative method which would await the progress of symptoms and preparation of the patient and environment for operation; and the number of deaths annually from ruptured ectopic pregnancy without operation is large. Ofttimes the character of the lesion is unrecognized, but quite often death results from delayed operation. Surely no surgeon would advocate delay in dealing with a divided femoral artery. The same positive indications exist for immediate operation in cases of ruptured tubal pregnancy. The surgical rule to cut down upon and tie the bleeding vessel without a moment's delay is as applicable in one case as the other.

In studying the results of treatment of intra-pelvic disease, it will be apparent that next to delay in operating, incomplete operations are the most disastrous. It is evident that the cumulative difficulties encountered by the operator are most frequently the results of prolonged delay, as has been already indicated.

The exploratory incision is a diagnostic resource of inestimable value. It has a great field of usefulness, and the knowledge acquired by its aid, converting uncertainty into certainty, opinions into facts, is a guide to action not possible by any other means. It is apparent, however, that the limitations of the exploratory incision will be narrowed in proportion as skill in operating improves. To a certain extent almost all operations for intra-pelvic disease are in their inception exploratory. But it must be conceded that many unfinished operations are classed as exploratory. It should be our aim to carry the operation to completion in every possible case. There is an ever-present temptation to avoid the immediate dangers of a severe, difficult and prolonged operation, at the expense of the deferred but assured result of a mortal disease.

In dealing with large tumors, ovarian and uterine, in operations upon the appendages for long-standing inflammatory lesions, the *greatest difficulties* arise from adhesions. These difficulties will be greatest in neglected cases of suppurative disease of the tubes and ovaries. Here all landmarks are lost, the pelvic tissues are agglutinated and fused into an undistinguishable mass. Injury to viscera and hæmorrhage are ever-present and often inevitable dangers. These are the operations most frequently left unfinished, and if the patient recovers from the operation, it is to succumb at last to the disease. It is remarkable how long some women can live and suffer with persistent disease of this character. In one case coming under my observation the disease had been in progress fourteen years. Discharge of pus had taken place repeatedly through rectum and bladder, with only temporary relief. The entire pelvic contents were matted together, making enucleation difficult in the extreme and rendering the result imperfect. Prompt resort to operative treatment would have prevented incalculable suffering and restored the patient to perfect health.

The influence of improved diagnostic and operative skill upon the results of pelvic surgery must be apparent to every one who has watched the progress of this branch of surgery. Formerly it was quite common to observe in the reports of work by representative special surgeons that thirty or forty ligatures were applied to bleeding points; that adhesions were divided between ligatures; and that tumors and broken down tissues were left as irremovable; or that the growth was not disturbed, as it was most probably malignant, etc. With revised methods and improved skill such practice has been replaced by careful, thorough and bold enucleation. Now, by means of forci-pressure, hot water and gauze packing, hæmorrhage from severed adhesions is controlled without exposing the patient to the shock of prolonged operation under anæsthesia. With these improved methods the number of incomplete operations has diminished, and as individual skill improves and operative methods are perfected, the proportion will be still further lessened.

There is another influence which is destined to be very potent in improving results now impaired by delayed and incomplete operations. As knowledge is diffused and diagnostic skill improved, the family physician will recognize serious pelvic disease at an earlier period, and advise operation. With improved results, both the profession and the public will cease to regard peritoneal operations with the fear of the olden and mortal era, and thus delayed operations will be lessened. This should be the aim of every conscientious worker, and it is the purpose of this paper to show how essential are *promptness* and *thoroughness* in applying the advanced principles of modern pelvic surgery.

Discussion.

Dr. G. Betton Massey, Philadelphia, thought it unfortunate that these two papers were read together, as their conclusions are very different. The paper of Dr. Ashton was the result of careful work, as I well know. The paper of Dr. McMurtry seemed to be a collection of dogmatic statements based solely on his own opinion. He urged a complete operation, and said that we could not always say a woman died on account of the incompleteness of the operation. It is a little behind the times to advise the practitioner to send all his cases to the abdominal surgeon every time they have a pain in the belly. I venture the prediction that in the future serious interference with the abdominal cavity will be limited to those cases in which pus has been demonstrated to exist in the pelvis. He wished to call attention to the ease with which a powerful electric light could be enclosed in a series of test tubes, one inside of the other according to the amount of heat. This can be inserted into the vagina and will light up the pelvic cavity. This light will penetrate a cyst, but will not penetrate a collection of pus, which is a means of diagnosis of the presence of pus. This light will penetrate living bone even better. We can notice light shining through our fingers on holding them up before a bright light.

Dr. R. B. Hall, Cincinnati, thought it impossible to determine the presence of pus in all cases, and that the prediction of Dr. Massey would not hold, and that this would be dangerous doctrine to promulgate. The doctor reported a case in point.

Dr. Joseph Tabor Johnson, Washington, D. C., thought the papers read, and others which have been recently published, teach us that we are not thorough enough in our operating.

Dr. Franklin H. Martin, Chicago, thought the paper of Dr. Ashton taught us how to avoid trouble. We should give much care to the treatment of raw surfaces in the intestine. These surfaces will readily take on adhesions. These should be covered with peritoneum if possible, otherwise covered with an omental graft. Stumps should be covered with peritoneum, which will also prevent attachments. Saline treatment is very important. In the Woman's Hospital at Chicago we endeavor to get a passage of fæces or gases during the first twelve hours.

Dr. Edwin Ricketts, Cincinnati, has had much benefit from the administration of strychnia in large doses in intestinal paresis. A case which he recently had looked very much like peritonitis, but after the administration of strychnia a large quantity of gas was discharged. The speaker could not agree with Dr. Martin as to the danger of adhesions resulting from the stump. Such had not been his experience.

Dr. W. E. B. Davis, Birmingham, Ala., did not think abrasions had such an influence on the causation of adhesions as claimed. Purgation twenty-four or thirty-six hours after operation will not break up adhesions. It should be done earlier. He considered it very important that the bowels be returned within the abdomen during the operation. In fibroids it is the adhesions which give symptoms, and it is unjust to blame these on the electrician.

Dr. E. P. Davis, Philadelphia, said the pathology of the peritoneum was a very important feature. Different portions of peritoneum have different powers of resistance. Iodoform seems to be least irritating to the peritoneum, next boracic acid. It is known that the peritoneum of dogs is different from that of the human being.

Dr. W. E. Ashton, Philadelphia: Obstructions are not always due to faulty technique; sometimes to inflammation which could not be prevented. Taking a graft from the omentum only made a point where the gut might pass through. Strychnia has been followed with very good results. I give one-fifteenth to one-tenth grain three or four days before and after section. It increases peristaltic action of bowels, clears them of fæces and lessens the danger of intestinal paresis.

Dr. L. S. McMurtry, Louisville, in reply to criticism, said that the observations and deductions made in his paper were based upon his personal experience in pelvic surgery, and were fortified by illustrative cases. He deprecated resort to operation in doubtful cases, and advocated most careful discrimination in deciding the question of operation in all cases; but he believed it equally an error to delay operation in clearly defined conditions requiring operation until the patient's chances of recovery are reduced or lost. Of course, there must be a restriction on early operation in fibroid tumors in accordance with the rapidity of growth and amount of hæmorrhage. When these conditions clearly point to the necessity for operative interference, the sooner it is done the better. When resorted to early, the appendages may be removed and the growth, as a rule, will be arrested and hæmorrhage cease. If hysterectomy is rendered necessary, the sooner it is done the safer it is for the patient. It has been demonstrated that electricity is a failure in the treatment of uterine myomata; and while these tumors sometimes disappear at the menopause, or sooner, without treatment, they often grow in spite of the menopause and treatment, and unless removed destroy the patient's life.

COLPO-PERINEORRHAPHY.

Read in the Section of Obstetrics and Diseases of Women, at the forty-third Annual Meeting of the American Medical Association, held at Detroit, June, 1892.

BY EDWARD W. JENKS, M.D.,
OF DETROIT.

INTRODUCTION.

In 1877, I read a paper before the Michigan State Medical Society in which were mentioned "some new procedures in the operation for laceration of the perineum" and Jan. 8, 1879, I read a paper before the Cincinnati Obstetrical Society, which was published in the *American Journal of Obstetrics*, for April, 1879, describing the same procedure as in the first mentioned article, the latter being entitled "Perineorrhaphy and a Description of a New Mode of Operating." This paper advocated a new mode of submucous dissection of the tissues or what is now designated flap-splitting.

This mode of operating was favorably commented upon by the leading medical journals of the day and the leading text books on gynecology published in this country continued for many years to sanction it. In that paper the cutting away of the flap instead of preserving it was advised. Subsequently I preserved the flap, and believing for a time my mode of operating as well as the preservation of the flap was original, so stated when asked regarding it by some of my friends, notably the president of this Association (Dr. Marcy), who mentioned the matter in one of his publications. But learning that others had also described saving the flap no claim has been made as to its originality with myself. The submucous dissection I described, or flap-splitting operation as now designated, was made several hundreds of times by me in public clinics, as well as by many others who had adopted it, some years before the flap-splitting operation of Tait or others had become known.

However, I *am not strenuous in claiming priority* in the mode of operating I described so long ago, as it is of little importance, for I am only one of the great multitude working in the field of gynecological surgery.

I am prompted to this historical fact as an introduction to this paper as the surgical procedures I made known fifteen years ago are occasionally referred to at the present time; and a late edition of a well known text book that had previously commended it by means of lengthy quotations and illustrations now dismisses it by a brief allusion as "too bloody."

Although repeatedly asked to write an additional paper I have had other fields to cultivate, and what seemed more important in surgical matters to engross my time and attention, but of late there seems to have been a revival of interest in plastic gynecological surgery.

DESCRIPTION.

The operation I make to-day and which is described in this brief paper is, I believe, a great improvement on my former method. It would hardly be possible for one to make hundreds of operations of any kind without finding a chance for some improvement either in the mechanical portion or in results obtained.

Of the surgical devices before the medical public known under the general title of perineorrhaphy the name is legion, consequently the merits or demerits of other operations than the one here described will not be considered.

It is not my purpose to discuss laceration of the perineum or the necessity for repair in detail. It is well known to every careful observer that rather extensive laceration of the perineum and vaginal walls occur in childbirth from which no bad results follow. Again it is equally well known that many discomforts and divers reflex symptoms often ensue from lacerations that at the time of their occurrence seem too insignificant to demand a passing thought or even a single suture.

It is to the consideration of secondary operations alone that your attention is called. I will state as a general proposition that operations are not demanded because of laceration *per se*, but when there are unmistakable discomforts that can be plainly traced to them, and health and comfort can only be recovered by restoring the torn parts to their normal relations.

The portion of the recto-vaginal septum known as the perineum supports the lower portion of the posterior vaginal wall, which in turn supports a corresponding part of the anterior vaginal wall. The lower portion of the rectum is sustained and the proper performance of its functions aided by the perineum. Four muscles, the levator ani, sphincter ani, transversus perinei and bulbo-cavernosus are here united; and it is the severance of these from their fellows on the opposite side together with the separation of the perineal fascia which produces the mischief, therefore laceration of the perineum and a portion of the posterior vaginal wall, whether partial or complete, may cause a variety of conditions, such as loss of vulvar integrity and impairment of the functions of the rectum, partial or complete incontinence of the rectum and bladder, increased and irritating secretions of the vagina and rectum and recurring prolapse of the rectum after operation for prolapsus recti, descent of the recto-vaginal septum or rectocele, a similar condition of the anterior vaginal wall and bladder or cystocele, and descent of the rectum. There are also various neurotic and sympathetic disorders which it is needless at this time to dwell upon.

I have seen quite a number of patients that had been operated upon with the result of having, to all external appearance, a perfect perineum but with a rectocele above the line of the dissection or flap-splitting that formed an excellent pocket for the accumulation of uterine and vaginal secretions, in which the neck of the prolapsed uterus was constantly macerating. In many of the cases where only a portion of the redundancy is remedied the only benefit seems to be, to provide a better support for some form of pessary to sustain the uterus and vaginal walls.

My own observation and experience, which I presume agrees with others, is that there are, at least in a general sense, four important ends to be attained in repairing the class of injuries under consideration: 1. To restore the loss of power and function to the lower portion of the rectum and vagina. 2. To restore the normal sustaining quality of the posterior vaginal wall for the anterior vaginal wall and bladder. 3. To provide as much support for the uterus as the perineum naturally gives. 4. To cure the many distressing nervous accompaniments.

Any surgical procedure which does not obtain such results to a great degree is not in a strict sense successful.

A perineum may be operated upon and, as far as external appearances are concerned, is successful, but if above the point of dissection there still remains a redundancy of the vaginal walls, or the restoration is not sufficient to support the anterior vaginal wall the operation is but partially successful. This is true whether the uterus is held up to the health line or not. There are so many causes operating to produce uterine displacement, that it is not as a general rule just to guage the success of an operation by the measure of uterine support it secures. For the reason that these partial operations are often insufficient and are not followed by the anticipated beneficial results, I have chosen to designate the surgical procedure I have been making for a number of years, colpo-perineorrhaphy. To accomplish the best permanent results it is essential that dissection of the flap extend as high within the recto-vaginal septum as there are signs of slack or redundancy of the posterior vaginal wall.

My mode of procedure is as follows: I first nick with the scissors each labium to mark either termination of the anterior margin of the flap and then, having introduced two fingers into the rectum and assistants making the parts taut, I insert the sharp pointed scissors near the juncture of the integument and mucous membrane in the median line or sometimes on one of the nicked lips and proceed to dissect a flap up the septum as far as redundancy of the walls can be observed. (Fig. 3.) It is important for the sake of making a more rapid and neat operation that the dissection be made in its entirety without withdrawing the scissors. When I first described my mode of operating in 1877, my friend, the late Dr. Albert H. Smith, devised a knife to take the place of scissors and subsequently I caused a knife to be made larger and more flexible than his. (See Fig. 1.)

The scissors which I have used for the past five years are slightly curved with blades completely overlapping each other, and both inner and outer edges ground equally sharp. I have found this form of blade is less liable to become entangled in submucous dissections than the ordinary shaped blade. (See Fig. 2.) These scissors can be used alternately in their proper capacity or with blades closed as a knife to dissect the flap more perfectly, as their sharpened outer edges and points render this an easy task, and there is a great advantage in their use in cases where there is much bleeding, as there is less hæmorrhage than with an ordinary knife.

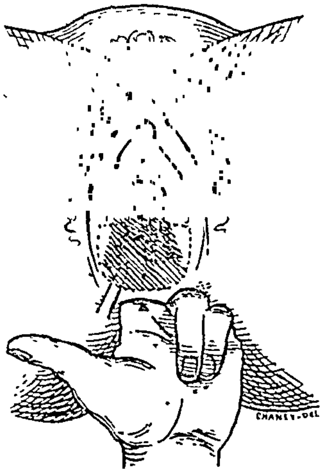

Figure 3.

Fig 1.

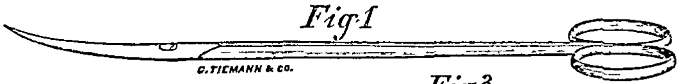

Fig 2.

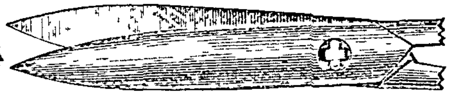
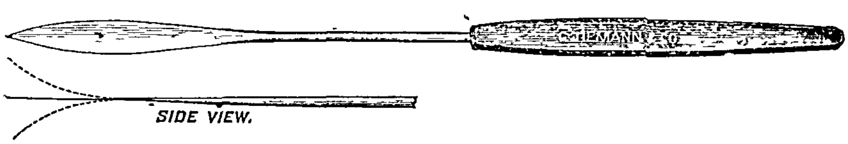
Fig 3.





One objection recently made to this operation is that it is bloody and sometimes one or more arteries have to be tied.

To my mind, if that is the case, the surgeon of the present day is not intimidated by a few small spouting vessels and if such a calamity occurs it is quickly and easily remedied.

In many hundreds of operations I have not been compelled to ligate vessels, all told, more than six times.

The next important step in the operation after the dissection of the flap is the insertion and adjustment of the sutures. I was led many years ago to adopt the method of the late Dr. Agnew of Philadelphia, in placing sutures in the perineum. Since then I have carried them deeper, higher and in somewhat different directions; still I do not claim any originality in this matter and wish the credit to be given to whom it is due.

No better results have ever been obtained than by silver sutures, but on account of their stiffness they cause more pain, therefore, in extremely sensitive patients I substitute the silk-worm gut, which possesses *the principal advantages of silver wire and is* not so unyielding. Kangaroo tendon is also a safe and useful suture, as its time of continuity is from *fifteen to twenty days.*

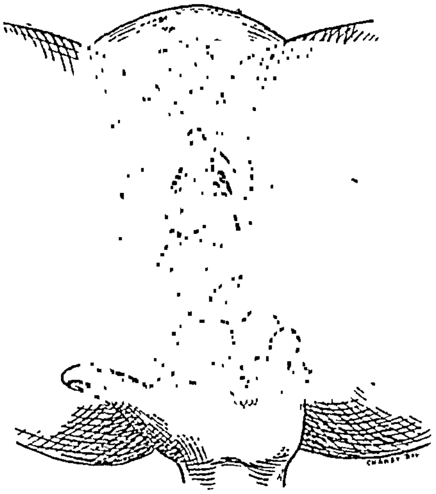


Figure 4.

The needles are a straight, flat non-cutting needle about two inches in length and a slightly curved Peaslee needle.

The latter is provided with a carrying thread which is number 4 or 5 braided silk about eighteen inches long. The former is used only for the short and superficial sutures which are threaded directly into the needle.

In the majority of methods of operating for incomplete laceration, the first and frequently the second sutures are shorter and of far less importance than the third or fourth, or fourth and fifth, as the case may be. But in my operation matters are reversed, for the first two sutures are the longest and most important. Indeed, for want of a better term I often call them *the parent stitches.* (Fig. 6.)

The first assistant lifts up the flap by means of a tenaculum hooked into the edge at the center. (Fig. 4.) Introducing two fingers of the left hand into the rectum to guard against wounding it, I start the needle in at the distance of one-third to one-half inch back from the denuded surface, and turning the point well toward the left buttock and the handle correspondingly as far in the direction of right buttock, I push it rather deeply into the tissue of the anterior ischio-rectal space, then upwards and finally inwards along recto-vaginal wall until it has been carried just above the highest point of dissection in the center, at which location or as near to it as possible the needle-point is brought out. When the point is about to come through, if counter-pressure is made with a blunt hook, the needle can be pushed through more easily, with less strain upon the septum and with less likelihood of pricking the anterior wall by the sudden emergence of the needle than without its use. As soon as the eye appears a loop of the carrying thread is pulled out by a tenaculum and the suture passed through it. When the needle is withdrawn one half of the first stitch will be *in situ*.

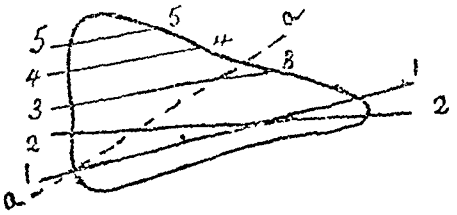

Figure 5.

The needle in then introduced in the same manner in the opposite side, the upper end of the suture threaded into the loop and the other half of the stitch carried to place.

For the second stitch the needle is started in about a third of an inch above the first and its point directed at first outward in the same manner as in the introduction of the first suture. Not quite so much lateral tissue is taken up this time, that is, the needle does not make quite so wide a side sweep for the second suture but passes more directly up along the recto-vaginal septum and when it has reached the upper third of its course, *crosses* the first suture and comes out on the vaginal mucous membrane about one-half or two-thirds of an inch above the central highest point of dissection. After drawing the first half of the suture into place the needle is introduced in the same manner on the opposite side for the second half of this stitch.

For the third stitch, a third of an inch above the second, the needle passes along the denuded surface till it reaches the line of junction of the septum and the flap, when it enters the latter at about its upper fourth, burrows across to the opposite side and down the denuded surface to the outside.

This stitch can sometimes be introduced in one continuous circuit, in other cases one-half at a time.

The fourth and fifth stitches are buried under the denuded surface as far up as the junction of the septum and flap where they pass under the flap without burrowing in it to the opposite side. With each of these sutures it is usually more convenient, although not necessary, to put in one-half and then introduce the needle on the opposite side in the same manner for the other half.

The ends of the sutures are now placed together and traction enough made upon them to determine whether the denuded parts are coming properly into apposition. At this time the flap will emerge more or less from the introitus and will frequently have the appearance of being much too long; the operator will consequently be tempted to pare off a quarter of an inch or more from the anterior edge, but this should not be done except in rare cases of great redundancy. This slack is disposed of by the gradual retraction of the flap during the process of healing and settling into normal relations. The sutures are now loosened again and the sixth stitch introduced which is designed to purse up the anterior side of the flap and also bring together the last of the denuded surface. For this purpose the straight thin needle previously mentioned is used. The needle is passed under the portion of denuded surface contiguous to the edge of the flap and thence into and through the latter to the opposite side. All the sutures are now picked up and slackened enough to allow the flap to be raised in order to clear out by the douche any clots that may have collected.

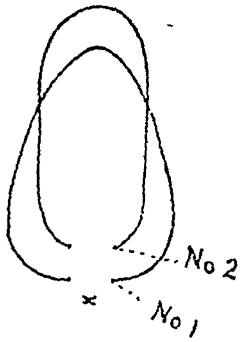

Figure 6.

The sutures are then all drawn up ready for fastening.

If silver wire has been used each suture is carefully shouldered and twisted. If silkworm gut has been employed the sutures may be either tied or secured by perforated shot.

Care is required in adjusting the first two long sutures not to draw them too tightly, otherwise they will cut in a little, and owing to their including so much tissue adjacent to the rectum, will be painful. The third, fourth and fifth sutures can be drawn more tightly. The sixth, again, should be but moderately tight, as the pursed up edge of the flap will not bear too much constriction.

Usually two or three superficial sutures of fine silk, horse hair or small silkworm gut will be required to coapt any raw edges turned out by the puckering up of the flap.

In case there seems to be any liability of hæmorrhage beneath the flap I place a strong silk suture by means of a Peaslee needle outside of the adjusted sutures and over the flap, which I retain for about twenty-four hours and then remove. (Fig. 5, *a*.)

These last are not absolutely essential but they give a neat appearance to the operation as well as dispose of surfaces for absorption or granulation. If silver wire has been used the ends may be massed together and inserted into half an inch of small rubber tubing to prevent them from pricking the patient.

In any surgical work, but especially in the plastic operations of gynecology, it is extremely convenient and helpful to an operator if he is ambidextrous. However, but few possess this accomplishment to a full degree and it is not really a *sine qui non* to skilful operating. Many expert operators do not interchange much the work of the two hands in the use of the knife, scissors and needle.

In this operation or almost any other for perineorrhaphy, the long stitch or stitches which pass from the outside up to the highest point of dissection in the vagina should always be put in one half at a time. If the dissection is made even approximately as high as it should be, a slightly curved needle cannot make the whole circuit at once, except in a patient with lax tissues and a broad space between the tubera ischiorum.

But even when it can be done it is accomplished at the expense of considerable strain upon the parts operated upon and the whole vaginal column.

I have constantly mentioned six as the number of sutures employed, but only because that is the number most commonly required. Occasionally five are sufficient, and sometimes seven or eight are needed.

As there are no exposed raw surfaces either externally or internally, but little dressing of any kind, and but few vaginal douches are demanded. Three or four are the usual number; one at the end of thirty-six hours, another on the fourth or fifth day, and another on the morning of the day the stitches are removed, usually the seventh. The external parts on the other hand, require about the same attention as in other perineal operations. Night and morning, and each time after urinating the soft parts adjacent to the line of union, and also the buttocks are carefully separated and the wound and the surrounding parts gently irrigated with sterilized water or a one to six thousand solution of bichloride.

The surgical procedure which I have here described under the name of colpo-perineorrhaphy, cannot commend itself on account of the consummate ease or rapidity in which it can be made. It is not as easily or quickly done as ordinary perineorrhaphy, nor even as the flap-splitting operation of which so much has been written of late.

But after essaying different operations from Baker Brown's to many of the present day, I have settled upon the method I have here briefly outlined as the best one I can make for the great majority of cases that present themselves to me for treatment.

In conclusion there are a few points to which I wish to direct attention.

1. Any single mode of operating is not adapted to every case of laceration of the perineum.
2. All other qualifications being equal that surgeon will be the most successful in this class of operations, who, instead of following hard and fast rules, possesses a mechanical skill which he can adapt to the peculiarities of each individual case.
3. The subsequent comfort of patients is not facilitated by superabundance of cicatrical tissue within the vagina; therefore the anterior wall, instead of being subjected to any surgical procedure for redundancy should be sustained by a restoration of the normal posterior wall.
4. The surgical operation here advocated has for its object, a restoration of the torn posterior vaginal wall and perineum to its normal condition, whereby there is afforded (*a*) support for the uterus to the full extent provided for in the vaginal walls; (*b*) support for the anterior vaginal wall and bladder; (*c*) support for the lower end of the rectum.

84 Lafayette Avenue.

THE American Microscopical Association will meet in Rochester, N. Y., August 9, and not August 10, as heretofore announced.

OVARIOTOMY IN THE PRESENCE OF PREGNANCY.

Read before the Section of Gynecology and Obstetrics, at the Forty-third Annual Meeting of the American Medical Association, at Detroit, Mich., June, 1892.

BY WILLIAM H. MYERS, M.D.,

OF FORT WAYNE, IND.

Seventy-six (76) years have elapsed since Recamier presented to the medical world the uterine speculum, and the dark age of uterine pathology was passed and a new era begun.

As in history, we progress by alternation, by conflict and by revolution, so were these the steps in medicine and surgery by which we have attained the advanced thought of to-day.

From 1816 to the present, a wide range of material has been submitted; brilliant at the time, but existing now as the residue, as merely a trace of a previous pathology.

Recamier taught that the primary element of uterine disease was inflammation and ulceration; Bennet, ulceration of the cervix; Tyler Smith, hyper-secretion of the mucus glands of the cervix; Meigs, retro-version; Velpeau, flexion; Lisfranc, congestion and engorgement of the cervix; Madame Bovine, uterine catarrh; Grailly Hewitt believes that all the ills of woman are due to uterine displacement; Tilt, ovarian peritonitis. I might in this connection refer to the labors of Goupil and Bernitz in pelvia peritonitis; for they were the first to teach us a correct pathology of this condition, and the secondary importance of cellulitis. We of the present accept with the greatest facility the doctrine that the peritoneum and the ovaries are the structures underlying nearly all of the phenomena presented in uterine disease, and we relegate cellulitis. The truth of this doctrine opened the field of intra-peritoneal operations, and ovariotomy, according to a recent writer, passed through three successive periods, a period of groping, ending with the successful work of W. L. Atlee, Baker Brown and Sir Spencer Wells; second, a short period of excessive specialization; and third, a period of popular adoption deriving its impulse from the introduction of antiseptics.

The treatment of ovarian cysts has been settled, but the presence of an ovarian cyst during pregnancy presents questions for our consideration. The doctrine advanced may be thus enumerated:

1. Non-interference.
2. Puncture of the cyst.
3. Induction of premature labor.
4. Porro's operation.
5. Ovariotomy.

In regard to the question of non-interference, in the light of modern surgery, we dare not entertain it, for the dangers of axial rotation of the tumor, rupture of the cyst, of impeded labor, rupture of the vagina during labor, far outweigh the dangers of the removal of an ovarian tumor. The exceptional cases reported, where pregnancy has coexisted with an ovarian tumor, and the woman has passed safely through confinement, are too few to be accepted as a precedent; for in a large proportion of cases, if the tumor be large, abortion will occur; if not, a lingering labor and still-born child will be the result, and the danger of sudden death be ever impending. In a paper by Doctor Playfair, published in the ninth volume of the Obstetrical Transactions, he reports thirteen (13) cases left to nature; seven (7) recovered and six (6) died. Spencer Wells enumerates three (3) cases where death followed the spontaneous rupture of an ovarian cyst in the sixth or seventh month. Doctor Barnes has seen one (1) case where death followed rupture of the cyst. In another case, the patient at last had peritonitis and died. Rokitausky refers to similar cases. I believe the almost unanimous opinion of the medical profession to be, that it is not safe to allow an ovarian tumor to progress without interference in the presence of pregnancy.

Puncture of the cyst, I believe, ought only to be resorted to where the cyst is simple and an operation for its removal would be impossible, as when called to the patient during labor. An ovarian cyst is more dangerous during pregnancy than at any other time, and that it will relieve the distension with a very slight risk to the mother, unless ovarian fluid should escape into the peritoneal cavity, or air enter into the peritoneal and into the cavity of the cyst. He also informs us that the cyst must be single, and if multilocular, tapping can be of little use.

I will here admit that there is no steadier brain in the medical profession than Sir Spencer Wells', equally at home in generalizations and in details. It is not my purpose to enter into any detailed criticism of his opinions, but we will refer to conflicting authority in subverting the view that "tapping will bring only a slight risk to the mother." In 1869 Thomas Nunnelly, of Leeds, England, delivered an address in which he stated, "in our infirmary of the last thirty-eight (38) cases of paracentesis for ovarian disease, ten (10) ended fatally." Stilling tells us that no surgeon should ever puncture an ovarian cyst. Storer says, "Never tap an ovarian cyst. It is a crime." If I were asked the question, "why not?" my reply would be, "after its adhesions form, it is useless and never cures." Charles Clay of Manchester, considers it useless, dangerous and to be followed only by evil. In a case of ovarian tumor, unilocular, that came under my own observation, tapping was resorted to in my absence and the patient died of peritonitis on the fourth day. Pozzi uses the following language: "Puncture is only to be resorted to when it is absolutely impossible to operate on the cyst." One of our latest authors, Bland Sutton, in speaking of paracentesis and of its several risks, says, "If air be admitted into the cyst during the procedure, or the instrument be septic from want of care and cleanliness; or if the fluid leak into the peritoneal cavity, and should it possess irritating qualities, inflammation and suppuration followed by fatal peritonitis may be the consequence. If these results follow the puncturing of an ovarian cyst in the absence of pregnancy, how much more likely to occur if complicated with pregnancy.

Induction of premature labor.—In 1869 this was advocated by Doctor Ruth, of London. Doctor Barnes had often met this complication by inducing premature labor, for the reason, he claimed, that nature could not tolerate the double uterus and a growing ovarian tumor. These opinions were expressed in in the Obstetrical Society of London in 1869, and at the close of the discussion, the President remarked that the sentiment was in favor of inducing premature labor. I may here state that the prevailing opinion now is that the induction of premature labor places the mother's life in peril and implies the sacrifice of the child.

Ovariotomy.—Tait states the accepted doctrine to be to perform ovariotomy and let the pregnancy alone. I believe this teaching to be good and the practice worthy of adoption. If the question were to be settled by statistics alone, I might refer to Olhausen; up to 1885 Schroeder had performed ovariotomy during pregnancy in twelve cases, Sir Spencer Wells in ten (10), Olhausen in eight (8), Tait in six (6). In only one of these thirty-six cases did the patient die. In this connection I will refer to Sir Spencer Wells' cases and the results to the mothers and the products of conception. Four (4) were operated upon at the third month; all the mothers recovered and pregnancy only interrupted in one case; three (3) were operated upon at the fourth month; mothers and children all did well; three (3) were operated upon at the sixth and seventh months: one woman died five days after the operation, one child born twenty-two days after the operation, one fœtus expelled nine hours after the operation, and one child born one day after the operation.

Where shall we interfere? There is a time in most cases when the balance of circumstances is favorable to operations, on the side of the patient. With a rapidly enlarging tumor and with pregnancy advancing it is easy to lose the golden opportunity by delay.

"That gentle physic given in time had cured me,
But now, I am past all comfort here, but prayers."

In 1872 Peaslee wrote: "If we delay until the health is somewhat impaired, we diminish the risk of peritonitis, which destroys one-fourth of all who die after the operation. This opinion was endorsed by Atlee, Bradford, Tyler Smith and Erickson. With this doctrine Peasley imbued the whole professional mind of America. He followed this practice, had seventy-eight (78) ovariotomies with thirty-nine (39) deaths.

We emerged from this doctrine in 1884. On a former occasion while reviewing this doctrine, I said that the time has gone by when we believe that the peritoneum has become more tolerent of injury and less liable to inflammation, when "The eye doth lose its lustre, and like the world's great warrior, the woman cries, 'Give me some drink, Titinius, as a sick girl.'"

Not often can an important doctrine gain immediate acceptance, but more likely the mental evolution necessary to establish, to recast old views and lead to new practice will be of slow development. "It often takes twenty years for the old people to make up their minds to leave the old farm."

The doctrine taught by Bantock, of London, with regard to early operation is as true in the presence of pregnancy as in its absence when he asserts, "I would urge then with all the force that the strongest conviction imparts that ovariotomy should be performed as soon as we can be sure of the diagnosis." This teaching is in accord with the first principle of scientific surgery. We inculcate the doctrine of early removal of calculi in the bladder, gall-stones in the cystic duct, and renal calculi, for the reason that there is no tendency to spontaneous cure and the surgical procedure becomes a necessity. In favor of ovariotomy in the early months of gestation we have this to say: The prognosis will depend largely upon whether the case is a simple or complicated one, the presence or absence of adhesions, and the length of time occupied during the operation. That the existence of adhesions greatly interferes with the success of the operation has been proven by Bantock, by referring to one thousand cases in Mr. Wells' practice. Adhesions, 599 cases, 165 deaths, 27 per cent. No adhesions, 401 cases, 68 deaths, 16 per cent. In his own practice, in one hundred eighty-five cases: Adhesions, 125 cases, 25 deaths; no adhesions, 60 cases, 3 deaths.

The Case.—In 1883, Mrs. B,, residing in Angola, Indiana, at the age of 17, was afflicted with a severe attackof scarlatina; sequelæ, ascites anasarca. Recovering from this, she was married December 24, 1889, pregnancy discovered in May, 1890. In September, 1890, she suffered intense pain in the lower part of the abdomen, depriving her of rest; she was unable to lie down at night. She was enlarging rapidly and with it her distress increased. She would not consult a physician, being a firm believer in the so-called Christian Science. `She at last felt compelled to consult a physician. Dr. Waller of Angola was called, and his diagnosis was pregnancy complicated by ovarian tumor. He requested me to visit the case with him, and I saw her October 1, 1890, and verified the diagnosis of Dr. Waller. We urged upon her the necessity of an operation. She gave her consent and we operated upon her October 5, 1890. After the usual aseptic precautions, an incision in the median line three inches in length disclosed an ovarian tumor on the right side, pushed up by the enlarging uterus. It had a broad pedicle, and it was in axial rotation. The physiological development was easily defined from the pathological by the difference in color. The tumor was multi-locular, weight of cyst and fluid contents probably ten pounds. The few adhesions were easily broken up by sponge pressure after the cyst was emptied. The pedicle was then transfixed and ligated by silk thread, and the cyst removed. The abdominal cavity was carefully washed out with warm water, a drainage tube inserted, after which the wound was closed and dressed in the usual manner, and the patient placed in bed. The shock was not severe, although she was restless for a few days, without alteration of temperature. October 12, uterine pains came on and the fœtus was expelled on the 16th without much suffering. This was followed by rise of temperature 102 degrees, chilly sensations. The local douche of hot water carbolized was resorted to twice in twenty-four hours. After the twentieth day from the operation, progress was satisfactory, and she is now enjoying excellent health.

In conclusion, gentlemen, the diversity of opinion concerning the treatment can easily be explained. The obstetrician regards premature labor with the greatest favor, the gynecologist abdominal section. From the latter, we receive innumerable instructions from time to time, a profusion of counsels under the sway of theoretical ideas. Success depends only upon a question of material; the personality of the surgeon is effaced, and if he works in a costly furnished room and with very expensive pieces of dressing, he can practice modern surgery and must succeed. Now I regard this as a dangerous doctrine that effaces the surgeon behind a question of material. Antiseptic surgery is governed by questions of material. To practice it successfully demands all the science of former days, more ideas and qualities unknown to our predecessors. Possessing these, the surgeon must be able to practice everywhere, and his success will increase in a direct ratio with his experience, and that is independent of antiseptics, but mainly governed by habits of cleanliness and fertility of operative resources that come by experience. John Homan says: "in regard to hysterectomy, I performed the operation much better than I did years ago, and my last cases nearly all recovered." Thomas Keith, speaking of his supra-vaginal hysterectomies, says: "Without the experience that ovariotomy has given me, I shrink from thinking what the mortality might have been."

AMERICAN MEDICAL ASSOCIATION.

SECTION OF PRACTICE OF MEDICINE.

First Day—Tuesday, June 7.

Isaac E. Atkinson, M.D., Chairman *pro tem;* James M. French, M.D., Secretary.

The proceedings of the Section were opened with an address by Dr. R. T. Edes, Chairman of the Section, read, in the absence of Dr. Edes, by Dr. E. P. Gerry. The title of the address was:

RELATIONS OF BACTERIO-CHEMICAL RESULTS TO PROPHYLAXIS AND THERAPEUTICS.

In opening the meeting of this important section, it is appropriate, as well as in accordance with the regulations of the Association, that some general remarks should be made in the nature of a recapitulation of recent advances in our science and art; a stepping aside, for a few moments, from among the bustle and hurry of practical work with its infinity of details, its confusion and worry; a looking over the field of battle from the outside; an orientation and correction of the compasses for a fresh start; or, as our commercial friends would say, taking account of stock for another year's business.

It is manifestly impossible, in the forty minutes wisely assigned as the maximum limit of time for these remarks, even to mention in *detail* all the important observations that have been made within the past year. Clinical observers and laboratory workers have all been busy in enriching our knowledge of almost every department of biological science. The task of recording and harmoniously arranging these must be divided up among many specialists and placed where they can be intelligently utilized by the busy practitioner.

I shall, then, only attempt, briefly, to advert to some of the special points in which it seems to me that scientific work is most fruitful not only of pure knowledge, but of practical application; and is most likely to lead far into the regions, at present unknown and unexplored.

If we find that much of the present accurate scientific knowledge has been preceded by theory and vague presagings, that practice has sometimes been right before theory could exactly say why, it is no new thing.

Our perception of the value of hints and suspicions is wonderfully quickened when it is found by the careful worker that some of the thousands of guesses emitted have really hit the mark.

The birth of a new science, or at least, of the perfection of methods of research so distinctly separated off from all former ones as to call for its own laboratories, its own specially skilled workers, and which give us a kind of result hitherto unknown, is, to be sure, not an event of the last year but recent enough to be well within the memory of young men.

Bacteriology, the recognition of specific growths, not only by their form as revealed by the microscope, but by their behavior, their habits of growth, as we know from a distance a grove of pine trees from oaks or apples long before we can identify them by their botanical characters, is, undoubtedly, both in medicine and surgery, the most path-making of modern discoveries.

While it is true, that in both great departments of the healing art there have been, for years, dim p sagings and theorizings of a germ theory, yet it is equally true that it is only recently that the various procedures, simple enough in themselves, have been systematized into a coherent and practically working whole, that consistent, definite, exact results have been brought about.

The surgeons can tell us that antiseptic surgery, as an art, began before bacteriology attained its position as an exact science; but, they will also say that the growth of both science and art has been going on in parallel lines, each confirming and improving the other.

And, in medicine, I think we may find that some of the older and less exact observations receive an explanation and are made more definite and decisive by the recent discoveries of bacteriology and organic chemistry.

The most beneficent of all specific forms of prophylaxis, that of variola was, as we all know, the result of a chance observation utilized by a careful and scientific mind entirely without the assistance of any modern instrument of precision except that one, without which all other laboratory apparatus is useless, the level head.

This single and signal success has been the stimulus to numberless attempts to imitate it in regard to other diseases of the same class, and will continue to inspire them until, with the assistance of the studies made more recently, success will be attained.

Close alongside of this study has come that of the organic substances, chiefly poisons, which is doing so much to enlighten our medical pathology, and which has received no slight impulse at the hands of the Chairman of this Section at last year's meeting.

The theory of autogenetic poisons, again, is not new. It is, perhaps, as old as medicine itself; but, when we are able to get the poison into the test tube and recognize its behavior with various reagents, we have assuredly advanced a most important step in our pathological knowledge.

The retention of various well known products has been long suspected as the cause of symptoms.

Bile must have been so as long as physicians have been aware of jaundice and its relation to the liver.

Urea has been tried and acquitted as harmless.

Uric acid is on trial, and evidence enough to convict it of a host of misdemeanors and, perhaps, crime is forthcoming.

But it is probable that we have yet to detect more guilty and better hidden criminals before we get at the real cause of uremic poisoning.

Fever is not, improbably, the effect of a poison, generated by inflammation, or by infection, which paralyzes the heat regulating centres. Whether the resulting rise of temperature is an effort of nature to counteract and neutralize the poison is a suggestion; but as yet, only a suggestion.

In cases of diphtheria a poison has been extracted from the membranes in two forms, an alkaloid and a poisonous albumen.

Similar poisons may be found in the blood; and, it is probable, that, in addition to the penetration of those formed in the membrane, renewed and continued formation may take place there under the influence of a special ferment. But the bacteria themselves do not go beyond the infected surfaces. All this has nothing in it startling to the clinician. It harmonizes with the views acquired by clinical observation, but it is a nearer and clearer view of what was before seen in clouds and uncertainty.

While we are bringing these accusations against the various pathogenic microbes let us, by the way, and as a digression, put in a plea of mitigation of damages.

It is not at all certain that many of the natural and physiological fermentations may *not* take place under the influence of bacteria.

Sterilized milk does not appear to contribute so actively to nutrition as in its natural state. It is, of course, less likely to carry disease; but, if it fails to carry health and strength, this negative merit is more than off set.

An extremely interesting series of observations has been made within a few years in regard to the appropriation of nitrogen from the air by plants.

It has always been supposed that vegetables derived their nitrogenous constituents from the decomposition of organic material in the soil or, if at all from the atmosphere, only indirectly and by way of ammonia.

It has been found, however, that some plants, among those actually experimented upon, the bean family in particular, are capable of growing in a soil absolutely free from nitrogen and of forming the usual nitrogenous compounds; thus, of necessity, deriving the necessary elements from the air. The power to do this is closely proportionate to the number of little tubercles or nodules found upon the minute rootlets of the plant, and these again, are dependent on the presence of a peculiar bacillus.

Thus, these lowly organisms that we regard almost wholly as pathogenic, control the first step in the process by which the vast stores of nitrogen in the atmosphere are transformed first into the albumen of the bean, and then, through this humble but intellectual instrumentality, into the highest cerebral tissue. So we must not condemn the whole family on account of the vicious habits of some of its representatives.

Among the most interesting of the secondary series of investigations which have grown from the original bacterio-chemical researches is to be placed that relating to immunity, showing under what circumstances and by what means the system is protected against infection.

It has been shown that the resistance to the invasion of a specific infecting bacillus is largely dependent upon the blood, although this by no means proves that the solids of the body may not have a share therein.

But the strife has waxed hot between those who think that infecting microbes are rendered harmless by the blood germs which may have attained peculiar qualities, or that they are swallowed by the leucocytes and thus arrested in their career of destructiveness.

Although the weight of opinion appears to be with the latter party yet there is no real reason why both constituents of the blood might not be active in the defense of the system.

This branch of the subject is as yet so very recent and so little settled that it will, undoubtedly, undergo modifications before becoming an integral part of acquired knowledge.

The immunity gained by various forms and successions of inoculation, that immunity of which the protection afforded by vaccinia against variola is the type, is, of course, a specific one, a protection against some one disease and that only, and seems to depend upon the use of some product of the disease producing germ. So that the growth of the germ up to a certain point produces something that prevents its further growth, as the alcohol, which is the product of ordinary fermentation, when it has reached a percentage of sixteen, more or less, checks the further growth of the yeast plant and the process comes to a stand still.

This form of immunity, with the single grand exception just spoken of as the type, has not been certainly produced in man. Many attempts have been made to procure the same kind of immunity from other infectious diseases, notably, diphtheria, tuberculosis and hydrophobia. I include this last among the unsuccessful attempts with a certain amount of hesitation, as there are those who believe that it should rather be added to the other class.

The failure of the attempt of Koch in the same direction has been distinctly and definitely recognized only within the last two years. The disappointment was, indeed, great, but greater than it need to have been had the modest and careful student been allowed to follow his studies to their proper conclusion, and the methods of the newspaper correspondent and the advertising quack excluded from a region which should have been governed by the most rigid scientific precautions and unbiased judgment.

We cannot help recognizing that there are some defeats more honorable than some victories. The bold attack of the careful and skilful Koch upon the chief destroyer of our race, failure though it may have practically been, calls for our most sincere and fervent admiration. No one who had the opportunity to watch for himself the effects of tuberculin and compare them carefully with extended reports of others and with bacteriological investigation carried on in the same direction, could fail to be convinced that we had at least a substance and, so far as known, the only substance that bore a definite and specific relationship to the tubercle.

It is no wonder and no great harm, that the breeze of popular favor, fickle as ever, should have veered round as usual, but the infliction of anything like ridicule or reproach at the hands of scientific men, upon a piece of work so logical, so careful, so thorough. based upon a received and firmly-founded discovery of the same man, a discovery in itself enough to place him in the foremost rank of biological investigators, seems to me an act of ingratitude and cruelty.

It is by no means beyond the bounds of possibility that modifications of the method may yet do us good service, but let us hope that the work will be completed before it is carried from the laboratory to the public prints.

The other form of immunity is, in some respects, less complete but more general, *i. e.*, the resistance which a healthy organism offers to disease, to any disease. It is well enough known to all practitioners that some persons are much more prone to infection than others, with so far as we can tell, the same exposure and the same dose of poison.

We know that this is not always and entirely a matter of the health and strength of system generally, but it is, certainly, very often connected with it, and it seems to me that the extremists are sometimes in danger of forgetting this form of immunity in their desire to emphasize the danger of infection. I speak, of course, especially of tubercle. Within the last few years we have had the doctrine urged upon us that the spread of tuberculosis is due almost solely to the inoculation of the tubercle-bacillus. In one sense, it probably is so. That is, a person to whom no tubercular bacillus has access, will undoubtedly be free from the disease. But how many such persons are there living within the limits of the United States, or, in fact, in any reasonably thickly settled country in the world?

Yet we do not all have tuberculosis. The experienced practitioner, the observing clinician, and indeed the intelligent public have always clung stubbornly to the fact that tuberculosis is more likely to attack some kinds of constitution than others; the life insurance examiner cannot be persuaded by any theory of accidental bacillary infection that a descendant of a tuberculous family is as good a risk, no matter what the surroundings, as one from healthy stock.

It is impossible to account for the distribution of phthisis solely and exclusively by the opportunities for infection. There, certainly, must be a special susceptibility, congenital or acquired, a readiness of the soil for the seed.

There are many facts of resistance and vulnerability in the human subject which is not easy exactly to parallel in the lower animals, so that experimentation cannot give so conclusive results, but there are certain peculiarities as regards race and breed which are to some extent parallel.

There are some recent experiments which show how much and how rapidly the resistance of the system to infection can be increased and diminished by agencies which affect the general nutrition. The observers used as their test poison the charbon or anthrax (Milz-brand) bacillus, and their subjects were certain animals which are normally but little susceptible to this poison, pigeons, cocks and white rats. They found that if pigeons, which possess this relative immunity, receive the poison when in a condition of extreme hunger they lose their power of resistance and die.

If they have been starving six days before the dose and receive proper nourishment soon after they do not die. If the starvation period has been longer than six days they cannot, as a rule, be restored.

The authors conclude from the short period of time, which is necessary to produce these effects that the loss of immunity arises rather from the want of nutritive and resistant material in the blood than from any wasting of the solid tissues.

It is one of the commonplaces of medicine that diseases rage with special virulence among the ill nourished; years of famine are years of disease. The history of typhus, it has been said, is simply the history of human misery.

The dispensary physician recognizes the underlying diathesis of many of the affections he has to treat as poverty and hunger, and looks to the diet kitchen rather than to drugs for relief.

It has undoubtedly not escaped the attention of most of you how common it is to see a family of children go through with several infectious diseases in rapid succession, as, for instance, scarlatina, measles and whooping cough.

This illustrates well the difference between the two kinds of immunity. A child has scarlet fever The development of the poison produces such change in the system that it is no longer susceptible to this poison. The disease is self limited, just as the fermentation ceases in the sugar solution when sixteen per cent. of alcohol, more or less, has been formed.

In addition to this the system, for some reason, is no longer capable, for months, for years, for a lifetime, of reacting to that particular poison. The patient has acquired a *specific* immunity. But while acquiring this *specific* immunity the *general* power of resistance dependent on the perfect nutrition of all the tissues, perhaps, especially the blood, has been decreased by the universally depressing effect of the scarlatine poison and the fever, so that to every other poison, beside the scarlatine the patient is more susceptible than before, and may then, in the presence of another poison, go though with the appropriate symptoms and acquire another specific immunity, say this time, as to measles. It is obvious how important such considerations must be in the matter of prophylaxis and therapeutics.

To go back to our original theme of tuberculosis, we cannot help recognizing, in the light of the more recent researches, the danger of infection to a considerable number of persons by the tubercle bacillus, whether in the milk or flesh of tuberculous animals, or that which is, probably, far more common, the dried sputum floating in the air and blown about everywhere as dust. This we can only to some extent avoid. Crowded rooms and conveyances and city streets are, of course, dangerous; but, how many can avoid them? Association with the tuberculous probably carries with it a certain risk (though, in my opinion, not a very great one), but affection and duty may be more powerful motives, even, than the dread of consumption.

Specific immunity from tuberculosis we cannot yet produce.

We find ourselves, therefore, with no lightening of the duty always imposed upon us in regard to tubercles, but with another added which bears not only on the physician and his patient's welfare but on the duty of that patient toward the community and that of the public health officers in the same direction.

The necessity of guarding against the tuberculosis of cattle is an important one. The phthisical patient should be made to comprehend the danger of spreading abroad the cultures of his bronchial tubes and cavities. But beside this, the demands of the old plan of getting the general nutrition into the best possible condition, either before or after the lodgment of the bacillus, is just as urgent as ever. The danger which cannot possibly be entirely avoided must be met by strengthening the defences. Fortunately, many of the same means, the most important, the most effectual, answer both indications. The air of lofty, dry plains is, firstly, relatively free from the infecting bacillus; secondly, a general tonic; and, thirdly, stimulates to increased vigor of respiration which renders the culture media of the bronchial tubes less appropriate for the growth of germs, should any find lodgment there. Until a prophylaxis dependent on a specific immunity can be obtained, it must be built up upon a general one; and, so far as possible, avoidance of the specific infection.

We used to be told that we should beware of treating the disease, that we should treat the patient who had the disease, and that disease was not an entity but a mere group of symptoms.

Now, looked at simply as a caution against a too vigorous and thoughtless therapeutics, this maxim does very well; but, as a fundamental rule of practice, it is one we are always striving to get away from.

Whenever we can get at the materies morbi we get rid of it, if possible, and it would, certainly, be highly unreasonable to do otherwise, provided, always, that the attempt do not endanger the patient more than the disease does. Thus, whenever we can we wash out the poisons of lead, mercury, arsenic and syphilis. We destroy or decompose or dissolve the rheumatic and gouty poisons with alkalies and salicylates.

We should do so with more poisons if we could get at them. Now, when the bacteriologist gets his seed from a certain disease, cultivates it, separates it from anything else, and then reproduces the disease by re-inoculating it, it seems to me that we have a very real and non-imaginary materies morbi indeed: and the attempt to kill or neutralize it is an eminently reasonable and proper one.

Unfortunately, human protoplasm is amenable to most of the same influences which act unfavorably upon organisms so far removed to the other end of the scale of being as the bacteria. In other words, most of our antiseptics and disinfectants are dangerous to the patient as well as to the disease germ; and, I fear, it will not be until the ideal disinfectant or group of disinfectants is found, that we shall be in a position to fight the germ without danger to the host.

It seems to me very problematical whether we are ever able to successfully attack the specific poison of most diseases after it has once fairly entered the circulation—that is, with drugs of the old fashioned kind. Some exceptions there are, already, to this rule. Our old friend, quinine, still holds its own and the plasmodic of malaria undoubtedly diminish and disappear under its influence.

And, again, it is undoubtedly, to a considerable extent, within our power and, probably, will be more so, to disinfect the intestines and other mucous surfaces which act as portals of disease, as the surgeon now does the cutaneous surface through which to make his incisions.

But, for most of the infections we shall have to wait for the special and peculiar results obtained from the bacillus, itself, which we desire to combat.

One paragraph in the rules of the Association demand that the Chairman of each Section should make suggestions in regard to the improvement in the methods of work.

Sidney Smith made a remark showing much knowledge of human nature, to the following effect:

"Benevolence is one of the most universal sentiments of mankind.

"A never sees B in distress without wishing C to relieve him." I might paraphrase by saying, "Scientific enthusiasm is one of the most common attributes of the physician.

"The medical orator never sees a good line of research without wishing the worker to follow it up."

There are many subjects upon which I should be glad to see laboratory work done; but, I am certainly not presumptuous enough to make any suggestions to the workers as to the direction or improvements of their researches. The founding of laboratories with all the appliances for following up the new lines of research mark an era in medicine.

We have reason to congratulate ourselves that educational interest and private liberality are doing for us in the United States a work which remains, to a considerable extent, at least, still in the hands of paternal governments in the old world, and that there is constantly growing up among us a class of men eager to enrich our science and capable of fully profiting by the advantages in their hands. So that clinical medicine and experimental research may go hand in hand, each making the other more careful and more accurate.

The experimenters are constantly furnishing to us data, sometimes of a more exact and scientific character than we clinicians are ourselves able to attain, data which may be of the utmost value in giving us new clues to the complicated tangle which we have to unravel in our study of human disease.

Our material and our methods, no matter how careful we may be, do not permit us the same kind of results or the same kind of precision which may be attained in the laboratory. On the one side the physician who wishes to work for the elevation of his calling, is required, as a scientific observer, to be accurate, to weigh and to count instead of to estimate and suppose, to correctly determine the amount and the location of the lesion, the height of the fever, the amount of the excreta, the species of the bacillus, the dose of the poison; then, also, as a sagacious practitioner, he must guage the factors which cannot be expressed in a numerical form, the weakness of tissues, the nervous instability, the diathesis hereditary or acquired and, finally, as guide, philosopher and friend, he has to allow for human frailties, the prejudices of family, race, religion, for vice and for ignorance, for interest, for caprice. Verily, the problems of the sick-room are not those of the laboratory.

It seems to me that the function of the physician, as an agent in the advance of biological science or a contributor to the physical welfare of society in the race, ought to approach as closely as the situation will allow to that of the laboratory specialist, and this is all I can offer as my suggestion as to improvements in the methods of work.

That clinical work should be freed, as far as possible, from the personal errors (amiable weaknesses, perhaps, but pernicious to the truth) into which almost every one of us is more or less easily led by ambition, the desire to excel, to originate, to feel that one has done a good or a great work.

That one should report what actually happens, not what he supposes the cause of success or failure to have been, not speculation but observation, and that he should be just as candid with failure as with success.

In other words, that the attitude of the physician toward medical *science*, not toward the patient or toward the medical *art*, should be as impersonal as he can make it.

Discussion.

Dr. David N. Kinsman, of Columbus, Ohio, in opening the discussion said: This subject of immunity is today one of pressing interest to the profession. I believe that any man who has anything to bring to the profession on this subject ought to do so, and, as I have been engaged in some experimental studies with a bearing in this direction, I desire to narrate the results.

The subject of protection is one thing, absolute immunity is quite another. We can by certain processes render a man partially immune; or we can by other processes render him more immune; but I doubt if we can render him entirely immune. As yet we have only the results of experiments from which to draw conclusions. No matter upon what animal we make the experiments, they have a bearing upon the whole subject.

The speaker then narrated how for some time he had been interested in making experiments in the production of immunity from hog-cholera by means of successive inoculations in the hog.

Dr. Didama, of New York, asked the last speaker whether any results could be obtained from the inoculation of fluid filtered from the cultures, or whether the inoculations have to be made with the bacilli.

Dr. Kinsman replied that they had not made an investigation of the effects of ptomaines and the other products of the bacilli, but that the inoculations had been made with the bacilli.

Dr. Dennison, of Colorado, arose to speak in regard to a statement which, he said, had emanated from Cincinnati. A physician in that city had stated that Professor Koch acknowledged to him that his tuberculin was a failure. After reading the statement the speaker wrote to Professor Koch to inquire as to its truth or falsity. Koch's reply states in the first place, that he has no knowledge or acquaintance with the physician who made the statement, and second, that the statement was utterly false. Tuberculin is not a failure; the failure is on the part of the medical profession. They have not come up to appreciate it. When they do, its success will be assured.

The speaker then referred to the culture experiments which have recently been made with the thymus gland as a culture-medium, by which the strength of the germs had been reduced so much as five or six thousand times. In this manner the poison of diphtheria has been experimented with. It is probable that the material which we use for the attenuation of virus will prove to be an important factor in the result which we attain.

Dr. Greenlee, of Kentucky, stated that he had had some experience with hog cholera, and that from his observations of its spread from a given locality to another, he had concluded that actual contact of the healthy animals with those having the disease was not necessary. He had often seen it spring up among hogs at a considerable distance from any known source of infection.

Dr. S. P. Kramer, of Ohio, remarked that he was happy to state that the individual who made the statement reported by a former speaker in regard to Koch's alleged acknowledgement that tuberculin was a failure was not a resident of Cincinnati but a visitor.

Dr. Kramer stated further, that in the production of immunity, two methods have been principally pursued. The one is that of the employment of attenuated cultures, as developed by Chauveau and Pasteur. The second is the method by which an albumin derived from the body of the germ is utilized. This, when brought in contact with certain principles contained within the animal organism, produces a body that neutralizes the toxic principle and reduces the pathogenic germ to the level of an ordinary saprophytic germ. In the first form, the antitoxin is formed by the growth of the germ within the body; in the second by the growth of the germ in the test tube. The first method, which may be called serum-therapy, has been credited with the cure of six cases of tetanus.

The next in order was a paper on

THE ETIOLOGY OF SPECIFIC DISEASE.

BY R. FRENCH STONE, M.D.,
OF INDIANAPOLIS, IND.

Mr. Chairman and Gentlemen:—If, in the present paper, I take issue with any of the audience in regard to recent or novel theories relating to the proximate causes of our most important diseases, be assured that it has been done with all sincerity, and with the kindest feelings for those with whom I may differ. The writer does not wish to be considered as actuated by a spirit of obstinacy, or unreasonable skepticism. Indeed, it is so much easier to accept the dictum of others, or to shift the responsibility of our views onto those who set themselves up as authority, than to formulate the lessons of our own observation and experience, so much more convenient to accept the thought of others, than to think for ourselves that natural indolence protests against the sacrifice. In medicine, as in all other pursuits of life, we are more inclined to simply acquiesce than to contradict, and usually there is so little encouragement to do otherwise that we rarely wish to intrude our own opinion, but infinitely prefer that others may take the lead and we will follow, however fallacious and misleading such guidance may prove. Hence, it may be said to-day, as in the past, the greatest bane to medical progress is slavery to so-called authorities, and that one of the greatest hindrances to the acquisition of real knowledge is a blind reverence for great names.

Asking your pardon for these introductory and somewhat irrelevent remarks we will now call your attention to the subject of our paper, namely, The Etiology of Specific Disease. By specific diseases is meant certain maladies possessing distinct characteristics, and which are not only engendered by special causes, but are supposed to be incapable of development without the application of a so-called specific cause for each disease respectively. Such, at least, is a strict definition of the phrase "specific" as warranted by the phenomena of infectious and inoculable maladies. According to our text-books there are 1,146 diseases which affect mankind, and require the study and attention of the physician, but from this extensive nosological list, less than twenty-five diseases are to be reckoned as belonging to the class under consideration. Yet these are known to cause nearly two-thirds of our total mortality. Medical history informs us that many of the pestilential maladies which scourged the world in past ages belong to this class and far exceeded the mortality of any which now prevail. Indeed, so great was the special increment of their spreading power and malignity that as *Niebuhr* has shown they not only decimated fleets and armies, but influenced the fate of cities and empires.

On the great plains of plague-stricken Asia, centuries before the Christian era, the query: "Shall such ills come by chance?" was then answered—

> "Like the sly snake they come
> That stings unseen; like the striped murderer
> Who waits to spring from the Karunda bush,
> Hiding beside the jungle path; or like
> The lightning striking these and sparing those,
> As chance may send."
>
> —*Light of Asia.*

Shall the intelligent physician of to-day meet this problem with no more rational interpretation than the ancient Buddhists in the earliest dawn of the world's history? Has the acquisition of long experience or the accumulated knowledge of the past thrown no light upon the cause and prevention of the maladies under consideration? In answer to this it may be said that the proximate cause of "specific" disease is now as it has ever been one of the most puzzling questions with which the human mind has had to grapple. It can not yet be said that we have positive knowledge as to the specific poison, if we may so call it, which produces scarlatina, diphtheria, yellow fever or cholera. The chemist can not detect in the atmosphere the cause of those infectious diseases which spread only through this medium, or *chiefly in this way, and to assert* that he can with certainty detect any peculiar substance in the blood of the most pestilential malady, that is its *positive etiological* factor would be a statement in advance of the facts of exact science. Neither by the microscope, nor by the minutest chemical analysis can we distinguish the pus globule of small-pox or of syphilis from the most laudable pus of the surgeon. Nor have the most delicate tests as yet shown any thing especially distinctive in the saliva of a rabid animal by which a specific disease of this class is communicated so certainly and positively by direct contact. The *agens morbi* of these diseases in our present state of knowledge is still an unsettled problem. But since it has been truly said that the "curse causeless shall not come" some explanation of the etiology of our specific diseases, like Banquo's ghost will not down, hence modern physiological, pathological, microscopic and chemical research has led to the presentation of several novel and plausible theories to account for the proximate and specific factors which give rise to the development of the diseases known to be of infectious or contagious character. Before their consideration, however, it may be said that it seems impossible to explain the development of any specific disease either *exopathic* or *endopathic* unless there be a recognition of certain predisposing causes of such maladies. We refer to pre-natal, conditional, and functional influences. There can be no reasonable doubt that some of the so-called specific diseases owe *their origin mainly to a hereditary transmission of a* proclivity to such disorder. This is notably true of tuberculosis, or it may be supposed that the inheritance lies in the tissues or tissue elements predisposing to certain diseases in certain families. In the spreading of epidemics, contagious and personal, susceptibility may be factors in a partly *conditional* sense. Influences which the old authors called "atmospheric," the various direct and indirect influences which relate to the normal succession, and occasional abnormality of seasons in respect to the isolation of our planet and of the temperature and humidity of air and earth are perhaps generally too vaguely regarded as elements of interest in the present question, but are possibly factors which no one who tries to solve these problems should omit from scientific consideration. Again, failure in the function of the lungs, the liver, the intestinal glandula, the kidneys and the skin to eliminate the *waste products* of the system must be regarded by the physiologist as one of the most potent predisposing factors in the production of every form of zymotic disease. Science is more and more teaching us that the "survival of the fittest" is applicable to specific disease, and that the victory will be on the side of the attacked in direct proportion to the normal condition of all the bodily functions, and that the factors mentioned not only favor the development and intensity of such diseases, but that without such influence their establishment would often be impossible.

The theories of the proximate and specific cause of specific diseases may now be noted in the order of their popularity, but inversely as we believe with respect to their true etiological import. We refer to the *bacterian* theory, the *bioplast* theory, the *chemico-physical* theory, the *nervo-glandular* theory, and the theory of *perverted vital force.* The first hypothesis attributes specific diseases to the agency of microbes or minute living objects. By most authorities these are all classed in the vegetable kingdom, and might be termed microphytes of the fungous order. By some they are dominated parasites. They are supposed to operate by producing changes in the structures affected— the blood, the cutaneous and mucous membranes, the cellular tissue, and glandular organs of a destructive character, deranging their functions, disturbing the processes of nutrition, of circulation, of calorification and secretion. Fever, loss of appetite, emaciation, prostration of the muscular and nervous forces being the usual results. Their mode of action suggested by the belief that they are living objects, is that by enormous multiplication they may act mechanically through their bulk, obstructing the capillary circulation, and by pressure on solid tissues cause their gradual destruction by robbing the blood of the pabulum used for growth of the mycrophytes, thus effecting emaciation by spoliation, and developing fever by conversion of molecular motion into heat, and deranging secretion by mechanical intrusion in the glandular structure; also engendering neurosal affections by similar action on nerve structure.

The discovery of the dependence of alcoholic fermentation upon the presence of the yeast plant (*saccharomices cervisa*), and the general resemblance between the symptoms of contagious maladies and the processes observed in the fermentation led to the use of the terms *zymosis* to express the action, and of *zymotic* to express the character of all those diseases to which microbes in general are supposed to give rise. But all such views for the present must be largely speculative. There are many points of difficulty requiring to be more fully illuminated by careful observation before the bacterian theory becomes an established doctrine in etiology. Many of these difficulties have been well formulated by Professor Hartshorn, of Philadelphia, and may be expressed in part, as follows:

1. Throughout all the investigations which have been made, or likely to be conducted, there remains the extreme difficulty, if not impossibility, of total separation between the microbes themselves and the matter of the vehicle in which they exist, such as blood virus, vitiated secretions, artificial culture material, or whatever it may be. All the effects ascribed to the bacteria, except their proliferation and mechanical intrusion, may, with equal propriety, be attributed *to the toxic* action of a portion, however minute, if the soil in which they have lived, whose modifications must be coincident with those which they undergo.

2. The absence of the characters belonging to definite organisms in the easily studied virus of small-pox and vaccinia is presumptive evidence against the probability of such organisms being essential to the causation of other enthetic diseases.

3. Bacteria are rarely seen in the incipient stages of disease, but after the blood has become impoverished, the secretions depraved or morbid products are undergoing decomposition they are found most abundantly, and are found most numerous in materials of a septic or infectious character after their period of toxic intensity has passed by.

4. Bacteria have been, however, sometimes abundantly discovered in healthy bodies upon the various mucous membranes, in the blood and it is said *in* countless number in fecal discharges without any specific disease following.

5. Suppuration may be produced without the presence of minute organisms of any kind. Bacteria have been found under Lister's antiseptic dressings without suppuration following. Pathological investigators (Paul Bert and Rosenberger) have destroyed all the microbes in a septic fluid and yet found it to retain its poisonous quality. Various elaborate investigations have proved that fatal septic poisoning can be produced in animals by the products of decomposition without the presence of living organisms, and experiments have shown that normal blood, when deprived of oxygen, in the absence of microörganisms, may acquire *septic* properties, and also that septicæmia may be induced by the injection of free fibrin ferment and other substances into the blood in the absence of such minute organisms. The same condition has also been produced by the subcutaneous injection of filtered saliva containing no microbes.

6. While Klebs and Koch *maintain the definite specificity* of each minute microphytic organism, on the contrary, Billroth, Burden, Sanderson and others assert their mutual convertibility according to the influences of environment, and Pasteur, Wood and Formad report experiments making it appear that modification by culture is possible, converting an innocent into a malignant parasitic organism, or a death-producing microbe into one capable only of causing a transitory and not dangerous local affection which, nevertheless, secures to the animal thus treated immunity when subsequently exposed to the deadly infection. But in none of these cases is there reported any morphological change, whatever, in the bacilli or micrococci experimented with; their capacity of reproduction through several generations being retained.

7. Other points of objection to the bacterian causation of disease relate to their specificity. While it may be conceded that like produces like is a rule of nature, and that different forms of bacteria may reproduce themselves, it does not necessarily follow that they can reproduce the disease which they may accompany. That *disease may be propagated like* plants and animals, by means of a peculiar form of these organisms would require the recognition of disease as an entity and not a physiological perturbation, but the analogy is so absurd and the assumption so unwarranted as to need no argument for its refutation. While this theory requires the belief that each specific disease is produced by a certain variety of these organisms and no other, it fails to explain *how* and *why* they are causative of a special disease or of immunity against subsequent attacks. If they act as a specific cause of a specific disease by their enormous multiplication in a mechanical way, through their bulk obstructing capillary circulation, or by pressure on solid tissues causing gradual destruction (as in tuberculosis), this is a property that is not confined to any particular form of such organisms, but is common to all of them. Then why should one particular variety engender one disease and not another, and why should they not continue to produce identical results as often as they gain entrance into the system?

It is held by Professor Jaccoud and others that the bacteria of infection are indistinguishable from *harmless* ones except by their effects, and that as the liquids inhabited by them are frequently infectious, they are therefore merely a medium through which contagion acts. In some instances becoming so infected themselves as to transmit the property through several successive generations. Again, some observers attribute the symptoms of many acute infectious disorders to rapid development of poisons similar to vegetable alkaloids by bacteria in re-moleculizing the normal fluids. Others hold that such animal alkaloids are constantly produced in the living body by albuminoid decomposition without such agency, and that the general function of minute cryptogamic organisms, when present, is of a beneficial or conservative nature in re-appropriating the product of organic decay.

Analogy in nature renders this scavenger theory more probable *per se* than that which holds them to be destructive parasites or poison-producers in the bodies which they may inhabit.

We may next briefly consider the vital germ theory, of which Lionel Beale is the chief exponent. Dr. Beale, *than whom no greater micrologist* has ever lived, uses the term *bioplasm* to designate the physical basis of life and growth. This consists, according to his views, *of separate particles* of less than $\frac{1}{1000}$ of an inch diameter, originating in the blood, and designed for the nourishment and growth of all the tissues of the body. *They are described as soft*, without color or structure, and enclosed in a colorless capsule, through which liquid pabulum passes for their growth. New bioplasts *are formed* by divisions of mature ones, and the new ones continue to grow by imbibition until they divide or contribute to the formation of solid tissues. *Microphytes*, with an average diameter of $\frac{1}{8000}$ of an inch, are considered by him as the lowest form of bioplasm, existing in all the fluid and solid tissues of both plants and animals, as well as in all kinds of mineral substances, and under all meteorological conditions (though dormant under some conditions of temperature and dessication). Being omnipresent, and, as he believes, indistinguishable from each other by any precise physical characteristics, he denies their relation to disease of any kind. Contagious diseases are attributed by him to degraded or perverted bioplasm descended from original healthy bioplasts. These constitute what he terms "disease germs," which have property of self-multiplication like healthy bioplasts, both within the diseased body and in any healthy susceptible body to which they may gain admission. These contagious bioplasts are extremely minute, having a diameter less than $\frac{1}{100000}$ of an inch, and though possessing "specific" characteristics for every disease, one cannot be distinguished from another, either by the microscope or by chemical analysis; neither can the healthy bioplast be distinguished from the diseased by any test except its effects. The disease germs referred to in this connection become noxious only after entering the blood and then passing into the solid tissues and secretions. According to this investigator, their multiplication in the body always elevates the temperature, and this may continue after the death of the victim, and that fever is due to this process, and not to oxidation of tissues; death being the result of change in the composition of the blood and derangement of capillary circulation. Beale's theory of migrating or transplanted bioplasts, in the writer's opinion, contains an element of truth, but has thus far received very little support besides that of its distinguished author.

On the supposition that *disease germs are only* abnormalities or deviations from healthy bioplasts which may be detached from one body and planted, while yet retaining vitality, upon another, and which may there undergo changes more or less morbid and destructive to the individual by whom they have been received, we certainly have a more plausible explanation of the transmission of contagious disease than that which is claimed by bacteriologists.

We will now call attention to the *chemico-physical* theory of Liebig, which embraces the doctrine that the *materia morborum* may consist merely of inorganic elements or compounds which, by entering the body and acting as chemical poisons, engender specific disease, and which affirms that the action of a *virus* is not essential to the development of a zymosis, or fermentation in the human economy. This hypothesis has been more clearly expressed in the phraseology of the late Dr. Snow, of London, as the theory of *continuous molecular change*. Chemists have defined this change to be decomposition by contact, or the action of presence. An illustration of this law is the power which small quantities of certain substances possess of causing unlimited quantities to pass into the same state. The phenomena of crystallization, the molecular motion that takes place in the operation of skin grafting, the diffusion of heat *from molecule to molecule, or the extension of a flame* from a burning body to combustible material within its reach, may be cited as physical instances, and *analogies of the operation of this law. Hence, if a* decomposing organic molecule is introduced into the human body, by this law of catalysis or induction it imparts its motion to other molecules with which it may come in contact.

The processes in fermentation, putrefaction, septicæmia and the multiplication of small-pox or syphilitic contagion from the smallest inoculation in the human body, are accounted for in a similar manner. Against the necessity of the action of minute living organisms to produce these morbid processes, the advocates of this theory urge that the above named changes, and many others like them, are produced in the absence of such organism by chemical agents formed in the body, such as *leucomaines* and *ptomaines*, those physiological and putrefactive alkaloids recently investigated by Vaughan and others, and that inorganic substances may develop such changes, *similar to the* action of sulphuric acid when it changes starch into sugar. In support of this doctrine it may be asserted, that the bacterian theory that every particle of contagious matter is (at one time at least) a living organism, and that only such living organisms reproduce their kind and the diseases which they accompany, is one which loses weight as an argument in view of the natural history of small-pox and analogous diseases.

The Nervo-Glandular Theory of the origin of specific disease has been plausibly urged by Dr. W. B. Richardson, of England, and is apparently an outgrowth of his studies of the above doctrine of Liebig concerning fermentation and its relation to nitrogenous material. He was convinced by experiments that zymotic disease could be communicated from one animal to another *by inoculation of various secretions*. He also succeeded in producing from such fluids alkaloidal substances of crystalline structure. *Inoculation of these in solution was followed by* the same specific disease as had yielded the alkaloids. (Leucomaines? or ptomaines?) Hence he concluded *that any animal* secretion might be made to yield a contagious principle to which he gave the name "septine," and the maladies thus engendered were designated by him as "septinous." The true *contagia*, in his belief, are therefore all of glandular origin, and the venom of serpents was suggested as a type of their source and action, the effect depending not on a multiplication of germs, but a catalytic influence, the agent changing other substances without undergoing change itself, and that the poison, therefore, is reproduced only in the infected and diseased body through its own secreting organs. He believes, also, that ordinary secretions may change character, and become poisonous without previous infection. For example, the exudation of ordinary peritonitis may give rise to puerperal fever, and typhus fever may be produced in overcrowded apartments by absorption of animal exhalation, and in this way contagia of various kinds may constantly arise *de novo*. In furtherance of his theory, Dr. Richardson emphasizes the fact that the number of separate communicable maladies has a close relation to the number and character of the secretions. As examples, hydrophobia is derived from the saliva of rabid animals; glanders from nasal mucus; enteric fever is traced to the intestinal mucous glands; diphtheria to the mucous glands of the throat, and scarlet fever to the secretion of the lymphatic glands, but admits that in some instances the blood corpuscles become the seat of the catalytic change. As Richardson maintains that communicable disease may arise without intervention of contagious matter, he supposes that the virus may arise through previous impressions upon glandular organs, and refers the origin of such cases to fear or anger, or other emotional disturbance, when no mode of communication can be discovered. In favor of this hypothesis much might be said.

It is now known that some of the most remarkable pathological effects may be artificially induced, either by drugs, the precisely localized and measured action of heat and cold, or by other agencies acting upon the nerve centres in the brain and spinal cord. And since it is admitted that the brain is not only the instrument of the mind, but that it presides over and controls the functions of all the other organs, its own disorders therefrom can hardly fail to affect them. Strong mental emotion may not only suspend or pervert particular functions, but is even capable of destroying life by arresting the action of the heart. Sudden mental worry may excite dangerous interference with digestion or start an abnormal cardiac rhythm. Mental shock can check or increase the action of the kidneys, and in fact affect all the secreting or excreting organs of the body. The influence of continued mental anxiety and the pernicious effects of habitual grief upon the nutritive functions, are plainly marked. Under its corroding blight the skin loses its freshness and grows dry and yellowish; owing to derangement of the liver the bowels become confined, and their habitual constipation is apt to be followed by absorption of fermentative and putrefactive gases and other noxious materials, giving rise to fecal toxæmia with all its consequences, and thus not only by reflex influence of local irritation, but direct influence through the blood, the vicious circle is completed by the further induction of disease of the brain and nervous system. Anger often brings on a convulsive attack, and insanity frequently follows close upon exaggerated mental effort, and especially upon violent mental emotion, whether of terror, grief or joy. The principle of moral contagion cannot be denied. The mind is affected by imitative influences. Thus chorea is excited in some individuals by watching choreic movements in others, and a single hysterical patient may arouse in others symptoms almost identical with her own, while the direct influence of the mental state upon existing disease, and in governing the susceptibility to others or favoring their development, is of the most potent character. For evidence of this influence in the genesis of specific disease the reader is referred to that most interesting book of Dr. Tuke's, entitled "Influence of Mind Upon the Body." Apropos to this subject are also the recent remarks of Sir Joseph Fayer, at the Sanitary Congress at Brighton, England, with regard to the expected invasion of the country by cholera. After denouncing quarantine and cordons as antiquated, worn out and obsolete devices, he urged that the true way to protect ourselves from this disease is to see that our homes are clean, that the water we drink is pure and the food we eat wholesome, and above all else *to keep our minds free from panic*. A panic state implies a disorganized vitality, and of its influence in aiding the class of diseases to which cholera belongs there can be no doubt.

GENERAL CONCLUSIONS.

Theory of Perverted Vital Force.—We must be somewhat brief in presenting the following conclusions as to the etiology of specific disease, as our views have been already emphasized as occasion occurred during our argument. It now remains for us to deduce several general facts which may serve to harmonize all of the theories presented, conceding to each its due importance, and out of all endeavor to construct one of our own which may serve to show how and why communicable diseases are made *specific*. The advocates of the bacterian, the bioplastic, the chemical, and of every other theory of zymotic disease, unanimously concede the fact that the presence of nitrogenous matter in a decomposing or readily decomposable state affords the best possible *pabulum*, either for the development of microphytes, the infection of bioplastic elements, the elaboration of animal alkaloids or the action of ferments. Hence a *common condition* which all these agencies require for their action in the production of specific disease is the presence of an excess of such pabulum in the blood of the individual attacked. Again, a careful study of the foregoing investigation as to the cause of the diseases under consideration certainly teaches that we must be on our guard against ascribing a specific etiological influence to the various forms of vegetable microörganism. For in certain cases these may have been in the first place non-existent, as when such a disease has been "autogenetic," and in no sense a derivative of antecedent disease of the same kind. This caution is especially applicable in regard to such an affection as erysipelas, which, although contagious, is also, on very good grounds, judged to be generable, especially during certain states of lowered health, induced by renal disease and some other visceral affections. Though not so positively known, it is by many deemed probable that a similar caution may be necessary in regard to more general contagious affections, such as diphtheria, typhoid and typhus fevers and cholera, which, though certainly infectious, may also be autogenetic. Among these diseases we might still mention several others which, although their ordinary or normal mode of spreading is by contagion, yet beyond reasonable doubt do sometimes arise spontaneously. We refer to such maladies as scarlatina and yellow fever, gonorrhœa, rabies and glanders; the two last, in fact, being only of spontaneous origin in the lower animals, from which they are communicated to man.

It would appear from the conclusions of Bastain and others, that in those complex, prolonged and continuous morbid processes constituting the phenomena typical of some particular infectious malady, that at some stage of this complicated chain of processes, and somewhere (that is in some organ or tissue, or in the blood) certain organisms may arise *de novo* and are not to be regarded as direct descendants of preëxistent organisms any more than we would regard the pus corpuscles met with in a case of purulent ophthalmia or gonorrhœa as direct lineal descendants of those which may have taken part in occasioning one or the other of such diseases. But admitting that the doctrine of *heterogenesis* is established and that of *archebiosis* or spontaneous generation is disproved by the experiment of Tyndall, it is by no means clear that the assumed mode of operation of microphytes in the causation of disease is the true one, or that their influence in the transmission of disease is not simply that of carriers of contagion the same as the non-vitalized chemical compounds of Liebig, the leucomaines and ptomaines of Vaughan, or the cast-off and altered glandular secretions and tissue elements of Richardson or Beale. It is not yet possible to say with regard to metabolic contagion what is the *essential constitution* of contagious matter, or what is the intimate nature of the transforming power which the particle of such matter exercises on the particles which it infects. Nor are we able, by actual demonstration, to say that contagion is a *material substance*. We know that the ancient philosophers in investigating the nature of heat regarded it at first as a kind of subtile matter which insinuated itself into the substances of bodies and resided there with greater or less manifestation of its presence, but heat is now regarded and proved by scientific observers to be, not a material substance, but simply a *condition of matter*—a phase of force, or molecular motion—and from the nature of its action *contagion* like the *force caloric* is, in the writer's opinion, a mere condition of matter and not a *material substance*.

As regards the question of the form of force which may explain the transforming power of the contagion of specific disease, science is still ignorant. Yet expert chemists express clearly enough the conviction that there exists a certain great unit of force in nature which lies beyond their power of analysis, measurement, or even of definite nomenclature. But in that most interesting, yet most difficult and hitherto almost uninvestigated branch of chemical dynamics, we are supposed to have our nearest clew to the scientific problems connected with the specific etiology of disease. Any theory which tends to explain the *rationale* of the processes under consideration must recognize the existence but perverted operation of the so-called vital forces. The theory which we present assumes the identity of the physical and vital forces. The physical forces embrace magnetism, chemical affinity, heat, electricity and motion. The vital forces are assimilation, combustion, animal heat, nerve force, and muscular contractility. All scientists now concede the correlation of the physical forces, that they are all convertible the one into the other, and the force, like matter, in any form can neither be created nor destroyed, and as presented to us in the universe, they are both indestructible and inseparable, perpetually existing, and unchanging in quality, yet ever changing in form. The intimate nature of force, however, is the greatest mystery of all unrevealed phenomena, visible only in its effects as manifested to our senses, it becomes at once an unknown and unknowable power, transcending all human knowledge and conception. We can only judge of its presence, therefore, by the peculiarity of its action, and the effects which it produces. If we accept the teaching of modern science, all matter is the vehicle of change, motion the result of change, and *force* the cause of change. Life, as we understand it, depends upon the presence of a material substance operated upon by force, resulting in movement, and the harmonious interactions of these conditions when applied to the animal body not only constitute life, but health, while its derangement as surely eventuates in disease and death. According to the demonstrations and conclusions of modern investigators of physical science, the *vis viva*, or life force, is simply the combined influences of the physical forces which are constantly changing in form during the various vital processes, the supply and action of the same being maintained by the food we eat, the fluids we drink, and the air we breathe. Let us suppose, for illustration, that the nutrient fluid charged with oxygen is placed in an *electro-positive* condition, at the same time the tissues are in an *electro-negative*, or magnetic condition, by which assimilation or chemical affinity is induced; this involves oxidation, combustion and molecular motion. Molecular motion is converted into (animal) heat, and heat is converted into (animal) electricity, or nerve force, and nerve force induces muscular contraction or mechanical motion, which in turn serves to assist and perpetuate the operation of the other manifestations of force, in that it maintains the respiratory function, contracts the heart and arteries, propels the blood to all parts of the system, and thus supply tissue waste and equalize temperature, as well as control the various secretory and excretory functions of the body.

Such are the different manifestations of the so-called "vital forces," the harmonious and normal operation of which constitute life and health, but when perverted will not only occasion disease and disorganization, but death either local or general, as conditions may determine. For example, if the blood from any cause becomes contaminated or deficient in oxygen, the forces governing nutrition, such as assimilation and combustion, will be perverted in their operation, waste materials, or materia-morbi will be developed, which may eventuate in morbific effects, either as irritation of nerve centers governing heat production, or local irritation exciting inflammation of various tissues or organs, as well as malnutrition and disorganization of various degrees and variety according to the extent of toxæmia, and the functional activity of those organs provided for elimination. For the materia-morbi thus accumulated may remain in a latent condition until equiliberation is commenced by increased oxygenation, and this may augment the amount of animal heat within the body, causing fever, which may in its turn induce pathological lesions, varying in character with its intensity, ten degrees of which mark the difference between life and death. Although force can only manifest itself by molecular motion, yet it may exist in two general forms known as potential energy and actual energy. Force stored up in certain conditions of matter, as in the tension of the particles of an explosive compound, such as nitro-glycerine, or in combustible materials as wood, coal and the food of animals, is known as potential energy, that is, power capable of being liberated for the production of effects. But when the nitro-glycerine explodes, the fuel is burned, or the food is oxidized in the animal body, the force they contain is given out in the form of effects produced, and the potential energy becomes actual energy, or in animal bodies, living force. Such is the nature of unoxygenized material in the blood constituting an *agens morbi*, in that it represents potential energy, becoming actual energy, and capable of producing morbid effects when subjected to zymotic action.

Force acting upon different forms of material substance will manifest itself in different ways, as chemical affinity, combustion, electricity, etc. Also force in its different forms acting upon the same material substance may give to a multiplicity of effects, as quantity and local conditions may determine. But force of any particular form, whether physical or vital, operating in a certain direction, producing certain results, *tends to continue its action in that direction, and the production of the same results as long as conditions favorable to its action obtain.* Thus the molecular motion imparted to a conducting wire from a galvanic battery may continue for thousands of miles. A spark of fire may destroy a city, and so the smallest quantity of chemical or perverted vital force arising from the blood in a state of zymosis, and conveyed by means of its own elements, may set up the same morbid action in other individuals whenever their blood is of a suitable zymotic condition, and it is operation of this law that gives us the *rationale of contagion.* But we find in the physical forces, so in the vital forces;—as in the great laboratory of nature, so in the individual organisms, that action is met by counteraction, and the force, however manifest, sooner or later tends to equiliberation. For this reason galvanic batteries become exhausted, fires must be fed with fuel, and zymosis ceases, and disease ends in the affected individual, and in communities when the material suitable for its action has been extinguished. Strictly speaking, therefore, *contagion is a phase of perverted vital force*, and this morbid influence does not imply the agency of microörganism any more than that of any other medium, vital or otherwise, which may serve to convey its action. The essence of contagion is not a material substance, nor does it necessarily require a definite agency through which it must operate, but is simply a form of force as imponderable in its nature as heat, light or electricity. Specific only so far as it naturally tends to operate in the same direction upon the blood of another individual when it contains certain constituents of identical character with those upon which it has been operating in the blood of the infecting individual, which is likely to be the case when individuals and communities are alike subjected to the same general and special predisposing causes of disease.

In conclusion it may be affirmed and reiterated that the agency through which contagion acts is not limited to any particular form of mycrophyte, or to the bioplasts of Beale, or to the waste products incident to tissue metamorphosis, for all may serve as carriers of a perverted vital force. While the types and varieties of infectious disease may be determined by the impressions made upon the nervous system, but influenced by the condition of the individual with reference to his powers of constitution, age, susceptibility, weakened condition of certain organs or tissues from previous disease or tolerance from like causes. And where the initial factor is due to accumulation of "waste products," then also by the character and degree of the defective excretion, and the route or channel by which the vital forces attempt its elimination. And finally, since any of the elements hitherto described as factors of contagion are infected through defective excretion, it necessarily follows that the character of an infectious or contagious disease depends upon the variety or nature of that glandular excretion which is most defective, and as these infected elements are most prone to elimination through those glands whose defective function has produced the blood contamination, we are thus afforded the *rationale* of the glandular involvement of specific disease. And if any such morbid elements were still under the dominance of the natural laws of *elective attraction* which appropriates from the blood certain elements to certain tissues or parts of the body, or that normal *repellant force* peculiar to certain excretory glands, their *deposition* in these localities would be secured, or their ultimate *elimination* (if the patient survived) through those glands and parts of the body identical with those from which they have been derived would be effected. And thus again would be stamped upon the disease its "specific" character.

Owing to the great length of the paper, only a part of it could be read, and it was passed without discussion.

(*To be continued.*)

SOCIETY PROCEEDINGS.

Gynecological Society of Boston.

Regular Meeting, held June 9, 1892.

The President, Augustus P. Clarke, M.D., in the Chair.

(*Concluded from page 52.*)

[25] Children's Hospital: The catgut is first scrubbed with yellow soap, and allowed to stand in ether 48 hours, in corrosive (50 per cent.) 48 hours, and finally preserved in the following solution:

Corrosive sublimate, gr. xv;
Glycerine, oz. ijss;
Absolute alcohol, oz. xxxj.

[26] Brunner scrubs the raw catgut with strong potash soap, then places it either directly in corrosive sublimate, 1–1000, or after leaving it one half hour in ether. It is finally stored in the following solution:

Corrosive sublimate,	1 part.
Absolute Alcohol,	900 parts.
Glycerine,	100 "

To test the aseptic condition of gut prepared in this way, Brunner manufactured gut from the intestines of an animal dead of anthrax; some he prepared and used without producing trouble, whereas the raw gut when inoculated into animals, caused fatal anthrax in all cases.

[27] Roswell Park immerses the catgut in benzine or ether; it is then dried and soaked in 1 per cent. sublimate solution for one or two days, again dried and placed in juniper oil and finally preserved in alcohol containing corrosive sublimate 1–1000.

[28] Billroth's Clinic: Catgut is first washed with potash soap, it is then laid in ethylic ether twice for 12 hours each time, then dried and sterilized in a dry chamber by raising the temperature to 250° F. Then it is immersed in a solution of

sublimate 1-1000 for 24 hours; it is kept ready for use in absolute alcohol.

[29]Wm. Goodell: The prepared catgut comes in greasy coils of a dark amber color. To dissolve out the fat these are placed in commercial ether for from 24 to 48 hours, according to the size of the gut; and if the gut is of the larger sizes the ether is changed *once*. The gut is *now* immersed for 48 hours in a 1-1000 alcoholic solution of corrosive sublimate. It is then wound on glass spools by surgically clean hands, and kept permanently for use in a mixture of 2 parts of oil of juniper to one of alcohol, which is occasionally changed. When needed for an operation, I transfer the requisite number of spools to a mixture of one part glycerine, which has been sterilized by heat, to 9 of alcohol.

This gives a greater smoothness and pliability. Thus prepared it will last in the tissues of the body from a week to ten days.

A study of these methods shows the preparation of catgut to consist of several processes.

1. For removing fat, such as scrubbing with soap, and soaking in ether, benzine, or bi-sulphide of carbon.
2. For sterilizing, by dry heat, boiling in alcohol or immersion in antiseptic solutions, or corrosive sublimate, chromic acid, carbolic acid, alcohol or juniper oil.
3. For tanning or altering the consistency of the gut so that it will resist the absorption by the tissues for a longer period, as the soaking in solutions of chromic acid.
4. For rendering soft and pliable, as by the treatment with glycerine.
5. For preserving; storing in solutions of carbolic and oil, juniper oil, alcoholic and watery solutions of corrosive sublimate, and absolute alcohol.

No one method comprises all of these processes, and therefore they may not all be essential for the perfect preparation of gut. Removal of the fat is necessary when the gut is to be sterilized by dry heat but not so in the other methods. If the natural oil of the suture is removed, it is usually replaced by storing the gut in an oily preservative fluid. The removal of the fat, may facilitate the sterilizing of the gut, and at the same time make it less irritating to the tissues, for the same reasons that ointments are abandoned in the dressing of wounds. Fat is not essential to the perfection of a suture, and therefore it may as well be removed.

Sterilizing by dry heat is a sure method; it requires more care; the gut is not so strong as that prepared by other methods. Boiling in alcohol requires less heat than in the dry method, and the tissue is hardened, both by the action of the alcohol, and heat. It is thus made stronger. Soaking in aqueous solutions macerate the tissue, tend toward their disintegration, and thereby weaken them, at the same time it enables the antiseptic substances used to penetrate deep into, and through every part of, the sutures, rendering them aseptic. Lister's method, which has proven quite effectual, owes much of its success to the action of the water in first softening the gut so that it can be thoroughly acted upon by a minute quantity of chromic acid.

Tanning, or hardening of the gut by chromic acid, is one of the processes of decided value, since it renders smaller size gut as efficient as larger sizes prepared in other ways.

Marcy uses Lister's process entirely, whereas Bryant objects to the method, saying it makes the gut resist absorption too long. It must be obvious to every surgeon that there are many instances where it is of decided advantage to have this suture resist absorption. Naphthol acts as a tan. Anything that will increase the pliability of a suture without diminishing its strength must be considered an advantage to its preparation. All animal sutures kept in alcoholic solutions, are apt to be hard and wiry. When soaked in water they become weakened.

If, however, they are preserved in alcohol, to which a little glycerine has been added, or immersed in a solution of glycerine at the time of using, they become soft and pliable.

The final preservation of sutures is important, as the strength depends much upon it. Kyle tested the strength of gut kept in sublimated alcohol and juniper oil, and the *effect of immersion in various solutions*. Gut kept in sublimated alcohol was found weaker than that preserved in juniper oil; this was especially evident by comparison of the larger sizes of gut. The small sizes of gut were of about equal strength. Pure alcohol increases the strength of both preparations; alcohol and carbolic (1-40), equal parts had little effect on gut prepared in juniper oil, but increased the strength of that preserved in juniper oil and immersed 20 to 40 minutes in alcohol, and watery solutions of sublimate, were lessened considerably in strength. Immersion in boiled water weakens both preparations.

From Kyle's test it seems that absolute alcohol increases the strength of the gut, and is its best preservative. Juniper oil is next, while sublimated alcohol is of the least value. Carbolized oil as a preservative has been abandoned in continental Europe.

[30]Drousart devised an operation for the treatment of congenital ptosis, which consists of the *formation of a tendon* out of connective tissue deposited in the track of a catgut suture. Ordinary catgut was absorbed too quickly, 2 to 3 days, so he used that treated by naphthol which [31]Dehenne has found to last twelve to fifteen days in the tissues. Naphthol is used as a *preservative*, and in *certain cases*, as the above, may be of special value.

The most important animal tissues which are used for the manufacture of sutures and ligatures are catgut, tendons from the tail of the kangaroo, opossum, rats, squirrels, whales, rabbits and some other animals. Strips of fascia and certain skins, as buckskin, parchment and chamois leather, also hairs from the tail of the horse. Of these, catgut is the most important, and most universally employed, because it can be so readily obtained, and kangaroo tendon the most excellent, as it is stronger; does not swell in the tissue; from its nature it is more easily made aseptic, and can therefore be more depended upon; and as it resists absorption much longer than catgut prepared in the same way (ratio 1-3), a finer thread can be used when this is of advantage, and in regions, as the cervix, where it is desirable the sutures should hold for a somewhat longer period than usual, the same size suture of tendon will remain firm several days after a suture of catgut has become absorbed. The great objection to kangaroo tendons is the difficulty with which they are obtained, and their cost.

In regard to tendons derived from other animals, many may be easily obtained and utilized to great advantage in all branches of surgery. [32]Dr. E. O. Belt has made extensive use of sutures derived from the tail of rats in ophthalmic practice. The tail is skinned, and soaked in water for several days, when on slight manipulation, it splits into perhaps a hundred fibres, each about 8 inches long. They are placed in alcohol, and about once a month, for two or three days at a time, they are soaked in a 1-5,000 solution of corrosive sublimate. Dr. Belt recommends these fibres in cases where a strong and fine animal suture is required. He says they are much finer than those prepared from the opossum's tail, which he has seen used by Dr. Chisholm.

The fine tendons in the tail of our common rodents are very strong, but they are too short to be used extensively as a continuous suture; however, they can be used as an *interrupted suture* and as a ligature. I have used the fine tendons from the tail of a gray squirrel to close wounds on the face, where it was desirable to avoid scar formation as much as possible. These tendons are as fine as the finest silk, and are very strong.

Discussion.

Dr. George Jones remarked that in the future the animal ligature would be in the greatest demand. He prepares the ligatures according to Lister's method. Whenever suppuration occurred in his practice he had always been able to discover that in their preparation sufficient precaution against sepsis had not been taken. Much credit is due Dr. Marcy for the persistent manner in which he has urged the use of the animal suture.

Dr. Jones stated that quite recently he had boiled catgut in refined petroleum. Dr. W. S. Brown prefers *silk ligature.* He uses the black iron-dyed because the white contains lead. He objects to the use of corrosive sublimate in the preparation of sutures. He also stated that strong alcoholic solutions would do less harm than dilute watery ones.

Dr. Burt prepares gut by Lister's method, diluting the chromic acid solution to 1-6,000, and determines by the color when he has effected this. He keeps the ligature dry, and has never had any trouble from gut preserved in this manner. He prefers the rough material used by clockmakers, because it is of more uniform strength. In the preparation of violin strings, the gut is sandpapered to make it smooth. This treatment renders it weak and unreliable for surgical uses. In operations for the repair of the cervix he prefers silk ligatures.

Dr. Clarke, the President, endorsed the use of the animal suture, and especially the ligature made from the kangaroo as prepared by Dr. Marcy. The speaker had been associated with some of Dr. Marcy's earliest cases, and could bear witness as to the superiority of this method. He further said that the silkworm suture, however carefully prepared, was not at all comparable to that made from the kangaroo. Speaking in reference to the use of the silver suture, he said that its employment often required a second operation which was dreaded by the patient much more than the primary. In his own practice he had never seen any untoward results from the use of animal suture.

The American Health Resort Association.

This Association met at the Tremont House, Chicago, June 30, and held three sessions.

There were present delegates representing Canada, Michigan, Massachusetts, Wisconsin, Florida, New Hampshire, New York, Pennsylvania, California, Illinois, Vermont, Colorado, Texas, Iowa, New Mexico and Central America.

A large correspondence was read by W. A. Chatterton, Secretary, from the absent members in various parts of the country.

The President, T. C. Duncan, M.D., of Chicago, then delivered a lengthy address, in which he outlined the good work of the Association, and how it was appreciated by the profession, enabling them to select climates adapted for the various cases of consumption. From reports received from the winter points, New Mexico had proven the most satisfactory This is of interest to the profession who are trying to save some of the "hundred thousand consumptives" who die annually in this country.

Dr. J. F. Danter, of Toronto, Canada, read a paper on the "Climates and Resorts of British America."

A report on the climate of Manitoba was read, from Dr. Clark, of Winnipeg.

The climate of New Brunswick was presented by Dr. J. Z. Currie.

From these reports it seems that there are a large number of consumptives in Canada, especially in the eastern provinces.

Dr. Adam Miller read a paper on sun spots and magnetic influence in disease.

The climate of Nebraska was presented by Dr. Brown.

The climate of California and its resorts was presented in papers by Drs. J. D. Hartley and S. W. Andrews, of Chicago.

Dr. W. P. Roberts, of Boston, read a report on the climate of New England, in which he reported that 15,000 die annually there from consumption.

"Consumption in Michigan" was the subject of a paper by Dr. Veenboer.

Dr. O. W. Gordon, of Council Bluffs, reported his disappointment in visiting various resorts, and spoke highly of New Mexico.

A report from Dr. A. Petin, of Las Cruces, N. M., formerly of Paris, was read in which he said they had almost constant sunshine, less than 2 inches of precipitation in 28 months, and that consumptives sent there were all doing well.

A report on the Adirondack region was read from Dr. Skinner.

Dr. B. W. James, of Philadelphia, contributed a paper on "Climate Maxims."

The climate of Costa Rica was presented by Dr. Buchanan.

Dr. A. S. Butler reported on the climate of Honduras.

"Texas as a Resort for Consumptives" was the title of a paper by Dr. Marshall.

Reports on mineral waters were presented from Las Vegas Hot Springs, N. M., Eureka Springs, Ojo Caliente Hot Springs, N. M., Costa Rica and Londonderry.

Prof. I. N. Danforth gave an address on "Mineral Waters, their Analyses and Uses."

He said the profession was being imposed upon by imperfect and fraudulent analyses. In the first stage of Bright's disease he thought that bland water should be used, and in the second Lithia waters.

Prof. W. S. Haines made a valuable report on Bacteria in Mineral and Potable Waters. In some mineral waters he found 2 bacteria to the cubic centimeter, and in some drinking water he found as high as 8,000.

A large number of members were admitted.

It was reported that a Congress of Climatologists would meet in Chicago next year, and it was voted that the Association meet with it.

The following officers were elected: T. C. Duncan, M.D., President, Chicago; J. F. Danter, M.D., first vice-President, Toronto, Canada; I. N. Danforth, M.D., second vice-President, Chicago; W. P. Roberts, M. D., third vice-President, Boston, Mass.; T. S. Hoyne, M.D., Treasurer, Chicago; W. A. Chatterton, Recording Secretary, Chicago; J. D. Hartley, M.D., Corresponding Secretary, Chicago; W. W. Van Baun, M.D., Philadelphia; Prof. W. S. Haines, M.D., Chicago.

The full proceedings and papers will be published shortly and all members will be supplied with these valuable and interesting transactions. For further particulars address

J. D. Hartley, M.D., *Corresponding Sec'y.*
1204 Milwaukee Ave., Chicago, Ill.

NECROLOGY.

Dr. James Sproat Green, of Elizabeth, New Jersey, died on the 1st, instant, aged 62 years. He was an alumnus of the University of Pennsylvania, class of 1851, and a member of this Association since 1872. After graduating he acted for two or three years as an assistant demonstrator of anatomy at his *alma mater.* He was on interne duty also, until 1853, at the Wills and Pennsylvania hospitals, after which time he took up his residence in Elizabeth. He gave special attention to orthopedics and abdominal surgery. He was repeatedly the president of the City Council of his city, and mayor for the year 1877. He was a founder of the Elizabeth

Hospital and a member of the surgical staff down to the time of his fatal attack, which was very sudden, by cardiac disease. He was on the point of going out in his carriage to attend a patient, when he was taken ill and in a few minutes had expired. He stood in the front rank of his profession in the northern part of his State. He had been for four years one of the board of managers of the Lunatic Asylum at Morris Plains. In 1890 he was chosen president of the New Jersey State Medical Society, an honor that befalls only the best and most worthy of the medical fraternity in that commonwealth.

DR. JAMES BARRON POTTER, of Bridgeton, New Jersey, died on shipboard while returning from Florida, on the 11th of June. He was a graduate of the University of Pennsylvania in 1847. He had passed the winter at his plantation near Fort Myers and finding himself to be failing in health, he determined to return to his home by the steamer from Jacksonville. He succumbed by disease of the heart, after the vessel had been about forty-eight hours out from that port. He was in his seventieth year.

NOTES.

AMETROPIA IN HORSES.—In London it has become a recognized branch of the optical business to supply spectacles for horses whose eyes are the seat of some error of refraction. It is claimed as a well authenticated observation that myopia is a prominent cause of the vice of shying, and the value of a good steed may be considerably enhanced by a cheap pair of concave glasses. But it is said that the principal use thus far made of horse spectacles is to make high-steppers of those animals whose walk in life is to be that of the hack or coach horse. While yet young the steed is given a pair of convex lenses set in stiff leather caps, entirely enclosing the orbit. The horse is misled thereby and sees the ground much higher than it really is; this has an effect upon his steppage that makes his motion admired and fashionable for cab and coupé purposes.

RARE FATALITIES AMONG PUBLIC MEN.—Prime Minister Honorable John Robson, of British Columbia, died in London recently in consequence of a seemingly trivial accident. The end of one of his fingers was caught and contused in the closing of a door of a hansom cab. The injured member was the little finger of his right hand. The injury was sufficiently severe to demand the amputation of the finger. Septic symptoms came on and a fatal issue could not be prevented despite the best of attendance. Mr. Robson was not in good health at the time of his arrival in London. Another gentleman, well known in the Conservative party in England, also died in the prime of life, namely Mr. Frank J. Woods, the secretary of one of the leaders in the House of Commons, Mr. Balfour. He died in ten days after being stung by an insect, supposed to be a gadfly. The injury was received upon the lip and was followed by an erysipelatous inflammation that resisted all efforts at cure. The attack may possibly have been one of malignant vesicle or charbon, of which our English cousins, fortunately, see comparatively little.

AN EMINENT LAWYER'S PORTRAIT OF HIS PHYSICIAN.—Hon. Thomas F. Bayard delivered the commencement address before the Baltimore College of Physicians and Surgeons, at its recent twentieth anniversary. His theme was to show the points at which the legal and the medical professions touch in the homes of misfortune and suffering, especially that affecting the mind rather than the body. In his long experience of life, he has witnessed that "brotherhood of the lawyer and doctor at a common fountain," that which never ceases flowing—the fountain of human sorrows and distress. Each profession has its function of cure, and the power of prevention. The necessities of modern social life make the physician the repository of a host of secrets which become sacred to him because these secrets are essential to his full knowledge of his patient's requirements. In enlarging upon these opinions, Mr. Bayard becomes more specific and personal. He refers to his own circle of acquaintance, and sketches the portrait of a physician who has carried consolation as well as medicines into the homes of his Delaware circuit:

"The physician," he said, "who thus relieves sorrow and anxiety by receiving them and sharing them can make no proclamation of his well-doing or the service he has rendered, and if he ever hears an applauding voice, it is now and then, but not always, 'the still, small voice of gratitude.' I doubt if there were any real physicians among the sect called Pharisees. Luke was called 'the beloved physician,' and in his history I find no suggestion that Luke was a Pharisee.

"You will perceive that it is upon the duties and responsibilities of physicians and lawyers as citizens that my comments have been chiefly made, for I never knew a really great physician who was not greater as a man—I mean, whose greatness did not rest upon his personal and moral basis, which elevated and strengthened his professional life, infused itself into the community in which he lived, and was in fact the underlying and pervading cause of his influence and consequent success in his profession. *It has been my personal fortune to know such a man. It has been my privilege and delight to accompany him in visits where his only medicines were the personal presence and conversation of the man himself.* He had shared and had lessened their anxieties; counselled the wayward; had led the sick back to health; cheered the weak-hearted; had 'rejoiced with them that did rejoice and wept with them that wept.' And I have seen such a man so surrounded by an atmosphere of love and trust, holding as it were the heart-strings of a family in his hands, their 'guide, philosopher and friend,' and then I realized what a moral force in society the profession, properly comprehended and properly followed, was capable of exerting, and how relatively small a part of its usefulness was the administration of medicine."

PROPOSED BIOGRAPHY OF THE LATE DR. AGNEW.—Dr. J. Howe Adams, of Philadelphia, has been desired by Mrs. Agnew to prepare a memoir of the late great surgeon, and the friends far and wide who can contribute unpublis incidents, stories, anecdotes, sayings and the like, will confer a favor by promptly sending their quota forward to Dr. Adams. In this respect, as in so many other situations in life, *qui cito dat bis dat*. To be timely and at its best, a memorial of this character should not be allowed to linger in its composition. Those who were his students in the fifties and sixties, and before the *Index Medicus* began to catalogue every bit of printed work a man does, will be most likely to furnish materials that are not already pretty well known to Dr. Adams. About twenty years ago, if we mistake not, Dr Agnew delivered an address before his class at the University, subject "Error in Diagnosis," about which his friends rallied him not a little, on the ground that all the errors for which confession was explicitly made were the errors committed by others, either his colleagues or his forefathers in surgery. He freely acknowledged his own fallibility in general terms, but the illustrative instances, as his friends chided him, were postponed for some other occasion or some other author. The address was a charming and informing one "all the same." It was on that occasion that Dr. Agnew took occasion to refer to the unseemly alacrity displayed b some practitioners to serve as expert witnesses against th fellows, in suits for malpractice. Dr. Agnew did not conten that all surgeons should be shielded, whether right or wrong, but he did maintain that before one practitioner testified against his brother, the former should have made himself conversant with every salient feature of the case in dispute. The man who cannot or will not do this much is unworthy of his place in the profession, and is liable to become a mer breeder of mischief. Dr. Agnew's influence, in this direction, was undeniably wholesome and just, and we trust that Dr. Adams will be able to illustrate it fully and strongly.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1271, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1271, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JULY 16, 1892.

BY-LAW IV OF THE AMERICAN MEDICAL ASSOCIATION.

The Publication of Papers and Reports.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

BRONCHO-PNEUMONIA OF INTESTINAL ORIGIN.

Five years ago SEVESTRE, from clinical observation alone, became convinced that broncho-pneumonia in infancy was occasionally of intestinal origin, and concluded one of his papers in the following language:

> "1. In children one or two years of age (and probably also of other ages), subjected to a vicious alimentation, there may occur a decomposition of the intestinal contents, resulting in a fetid diarrhœa and an infectious enteritis.
>
> 2. General *infection may* follow, and particularly pulmonary congestion and broncho-pneumonia.
>
> 3. Intestinal disinfectants, especially calomel and naphthaline, are the best means of relieving the diarrhœa, and of preventing pulmonary manifestations."

The work of his pupil, LESAGE, we reviewed a few weeks ago. More recently, two others of his pupils, GASTON and RENARD[1] have contributed the results of their work in the same field.

The chief characteristic of the trouble is the occurrence of the pulmonary disorder as a complication in the course of an existing diarrhœa. The cases usually occur in infants who have been badly fed. After more or less prolonged dyspepsia, diarrhœa *sets in and is characterized by frequent stools*, green, white, or yellowish and very putrid. In from two to six days broncho-pneumonia appears, and is ushered in by more or less fever, by cough and dyspnœa. Very young infants lie quietly upon the back or side with the thighs flexed upon the abdomen. While in older children some interest in surroundings is manifested. Often the abdomen is distended with gas and is sensitive to palpation. Gurgling occurs in the right iliac region, and the skin is flaccid and non-elastic. The tongue is white, covered with a thick grayish coating in the center, and red on the edges. The stomach is dilated with gas, and the spleen is often perceptible on palpation. Fever, which is sometimes wanting, varies between 102 and 104 and is very variable. The cough varies a great deal, and the dyspnœa, not usually intense, is shown by respirations varying from 20 to 45 per minute. The physical signs show broncho-pneumonia, but vary greatly from day to day. The disease lasts usually from one to two weeks, but may be prolonged to two months.

The authors describe *four forms of the trouble*: The supra-acute or choleric form; the grave or typhoid form; the prolonged or remittent form; and the light or common form. The first form is rapid and terminates in two or three days, the patient dying in an algid stage. The typhoid form lasts two or three weeks, has a quite constant temperature and rather less diarrhœa. In the remittent form, which SEVESTRE has described very carefully, the temperature remains elevated for two or three days, and then drops for a like period, when it again rises. These exacerbations and remissions may occur for four or six weeks, and each exacerbation is accompanied by a new patch of broncho-pneumonia. The diagnosis is not usually difficult. The appearance of fever and cough in the course of a fetid diarrhœa, in a badly fed or bottle fed baby under two years of age, should raise the suspicion of a broncho-pneumonia of intestinal origin. Generalized bronchitis gives less fever, and no diarrhœa. Frank pneumonia is relatively rare, and should be made out by the physical signs. Pneumonia complicating acute infectious diseases is readily differentiated by the accompanying conditions. Typhoid fever is difficult to distinguish; attention should be given to the rose spots and, in the authors' opinion to the temperature curve. Tuberculous broncho-pneumonia it may be impossible to differentiate.

---

[1] Rev. Mens. des Mal. de l'enfance. May, 1892.

Some interesting pathological work on this subject has already been done. LUBARSCH and TSUTSUI, in a case of diarrhœa complicated with pneumonia, have found, in both the intestine and the lung, the *bacillus enteridis* of GOERTNER. GILBERT and GIRODE in a case of cholera nostras have found the *bacillus coli communis*, associated with other forms, during life. CHANTEMESSE and WIDAL in six cases of typhoid fever have found the *Eberth bacillus* in broncho-pneumonia. LESAGE on the contrary asserts that pulmonary lesions complicating enteritis are always due to the presence of the *bacillus coli* in the lungs.

The pathological observations of the authors were made upon twenty-six cases of broncho-pneumonia with infectious diarrhœa. They made cultures from the stools and also from the pulmonary juice, which they obtained by punctures made into a pneumonic spot, during life.

The stools, naturally, gave various forms; among them were observed the bacillus coli communis, bacillus subtilis, bacterium termo, bacillus enteritis of Goertner, and diplococci. Of the 26 broncho-pneumonias examined, 16 gave only a single species of microörganism, 5 showed several species, and from 5 no cultures were obtained. Where pure cultures were obtained they were as follows:

Pneumococcus,	8	times.
Staphylococcus,	3	"
Bacillus coli,	3	"
Encapsulated bacillus,	2	"

The other five cases showed:

Pneumococcus and staphylococcus,	3	times.
Staphylococcus and bacillus coli,	1	"
Pneumococcus and bacterium termo,	1	"

From these observations the authors conclude, 1. That in the majority of cases, broncho-pneumonias occurring in the course of the infectious diarrhœas of infancy, are secondary, and are due to superadded microörganisms, and (in some cases only) are due to the specific agent of the infectious diarrhœa. 2. That in the majority of cases, the specific agent of the diarrhœa, favors by its secretions, the virulence of the parasitic species normally contained in the buccal cavity, and renders them pathogenic.

From further experiments on lower animals, which space prevents our reviewing here, the authors hold, that the bacillus coli is capable of establishing a true septicæmia, which in the infant starts in the intestine, and is provoked by diarrhœa. The bacillus coli passes from the intestine to the lungs by way of the lymphatics and blood vessels, and in this way produces the lesions of these organs.

In the lungs the ordinary lesions of broncho-pneumonia were found and in other organs generally, congestions with tumefactions, or granulo-fatty degeneration of the cellular elements, such as are commonly met in acute septicæmias.

Such observations as the foregoing are very valuable, and exceedingly suggestive. They seem to open the way to a more rational handling of a certain class of broncho-pneumonias. If clinical experience counts for aught, it would seem that the pulmonary lesions of intestinal origin are not limited to pneumonia; but that acute bronchitis is not infrequently traceable to a similar origin.

This work is particularly interesting in connection with the subject of typhoid fever in infancy.

That typhoid fever occurs more frequently in infants than was formerly supposed is coming more and more to be admitted. When it does occur the bronchial symptoms are usually exaggerated, and pneumonia sometimes supervenes. While typhoid in the infant can not be recognized clinically in a given case unless the peculiar eruption has appeared, it would be going too far to say that the absence of the eruption proves the absence of typhoid.

The appearance of the tongue which authors have described, is exactly that found in typhoid fever in the infant, and their grave or typhoid form is highly suggestive of the so-called enteric fever. Again, the relation of the bacillus coli to these cases furnishes food for conjecture, for RODET and ROUX still claim that the Eberth bacillus is but a modification of the *bacillus coli.*

THE "BREATHING" HOSPITAL.

How to make a hospital, or other public edifice where fresh air is a prime desideratum, renovate its atmosphere with proper rapidity is a question which is being answered better and better each year. The *Medical Press*, in treating of some recent devices, says that considerable gains have been made at the numerous public buildings where large fans have been put in, "but the results are generally less satisfactory than those obtained in industrial buildings, mainly because the ventilating engineer is not allowed to handle a public building *so as to make it breathe in the same free way* that is easily permitted in a factory, where æsthetic and other nice points can be left to take care of themselves." This is a most happy expression regarding the free full breath which such structures as hospitals should be competent to take, and take again, at definite respiratory intervals. One of the latest devices that has come up for examination and trial is one in use at Victoria Infirmary of Glasgow, the operation of which is to sift, and at the same time dampen, the inspired atmosphere before it comes into contact with the heating coils. Here we have an analogue of nasal breathing in the human subject, which is admittedly the normal, and as compared with "mouth-breathing" the less dangerous sort of inspiratory act. The nose-breathing of public buildings is contrived in this manner: The air is renewed six times in each hour; before it enters the wards it is filtered and washed by being passed through an air-washing screen of cords, formed of horse hair and hemp, closely wound over wooden rails at top and bottom, forming a close screen sixteen feet long by twelve feet wide or high, affording nearly two hundred square feet of artificial Schneiderian surface. There is a constant trickling of water down and over this screen, rendering it wet at all times, thus aiding in the detention of all dust and soot that would otherwise pass through into the wards. When once these filtered particles have adhered to the wetted cords, a current of air of considerable violence is not competent to carry them through the screen, but the dripping water carries them downwards into the sewer. An additional cleansing of the screen is provided for in the use of the following neat contrivance: An automatic flushing tank, of twenty gallons capacity, is fixed at the head of the screen and timed so as to empty itself once an hour, night and day, and flush away all particles that tend to clog the inlet. The Infirmary is located in a wholesome section of the city, near to the Queen's Park, yet the screen entangles a very considerable number of soot particles from the supplied air. One of the properties of this device is said to be the clearing up of the admitted air in times of foggy weather. Last winter when there were many days of dense fog, the air within the wards seemed peculiarly bright and clean. This nearly rounds out the suggestive simile of the "nose-breathing" system of ventilation, except that the air is warmed before it advances much further—and this done by coming into contact with steam-heated coils. But this is so self-evidently physiological and so wanting in novelty that no further comparisons are needed.

The ducts for the admission of the heated purified air are wide and shallow, cut into the wall about five feet above the floor; their direction is upward. The outlets are at the floor-level. Some analysis of the air, taken at three feet below the ceiling, discovered no organic matter, and the air of the ward generally was exceptionally free from microbes and molds.

The editor of the *Press* suggests that the time may come when the air will be cooled, by the use of ice, during the heated term, as well as warmed in winter as is now done. The claim is made that the patients are absolutely freed from exposure to draughts. Another suggestion is made that fever hospitals, and all places where small-pox and communicable diseases are treated, may so arrange their exit air-ducts that all the expired air shall be burned, or passed through fire, on its way into the outer world. There is at least one organized ventilating company in England which professes to be able to carry out in a practical way the above theories that our public buildings can be made to breathe in a vivifying and purifying manner.

OSTEOPLASTIC THERAPY OF SPINA BIFIDA.

The occurrance of a *spina bifida* without other deformity has been placed (Wernitz) at one in every thousand births. This makes this error of development a conspicuous object of therapy, not only on account of the interest of the parents, but from the quantitative value of the patients. Up to the present time, very poor results have followed except where the boney defect happened to be small. The obliteration of the meningocele has too often been followed by a return of the tumor. This return is due to the stretching and giving way of the muscular and connective-tissue covering of the cord, and these returns give the indication for successful treatment.

The treatment of defects in the spinal arch by an osteoplastic operation was proposed in 1885 and successfully carried out in one case by Dollinger. He divided and brought together the rudiments of the spinal arches in the lumbo-sacral region and succeeded in covering in an exposed cord. Since that time a few cases have been reported at considerable intervals. In a recent number of the *Centralblatt für Chirurgie*, Bobroff[1] of Moscow, reports a very significant operation with a remarkably favorable result. The patient, an eight year old boy, had a considerable defect in the lumbo-sacral arch, and a myelomeningocele as large as a base-ball. It could be depressed so that half the fluid disappeared, when the child complained of pain and syncope. There had been complete incontinence of urine and feces since birth. After the ordinary method of reducing the sack had been accomplished through two lateral openings, a flap of bone with the overlying muscle was raised from the remnants of the arch. This flap was about three centimetres square on each side; with these two flaps the defect was covered and the pieces held in place by bone-sutures. There was union everywhere in a few days and after three months the patient began to control the sphincters.

This happy example of rational treatment should stimulate surgeons to resort to the osteoplastic operations in all suitable cases. It is necessary to remember that most defects in the mural arch are accompanied by defects in the cord itself, and that in order to be successful the surgeon must understand, as an embryologist, the exact conditions under which the defect or arrest of development occurred. In the majority of cases the meningocele will be found continuous with the central canal of the cord and the *cauda equini* will be ribbed out in the cyst wall. The cord itself will be found deformed and unequally developed, and the remnants of teratoids must be looked for. There are, doubtless, cases where the defect in the bony arch is so small that an osteoplastic operation is unnecessary. There are cases in which the defect is so great and is accompanied by such extensive defects in the cord that a successful restoration of the mural arch would leave the patient in a pitiable condition still; but between these two extremes there is certainly a wide field for the procedure.

---

[1] A. A. Bobroff. Ein neues osteoplastisches Verfahren bei Spina bifida, No. 22 p. 465—467.

The indications for treatment in these cases are the more imperative from the serious effects which the wearing of a meningocele has on the nervous system, and the uniformly progressive nature of the defect itself. The child's life should not be endangered by the lesser operation, when hope of permanent recovery lies only in the restoration of the bony arch. The child's life should not be endangered by months or years of waiting, because they are months or years of danger of rupture and infection while the bones are becoming more and more difficult to manipulate and the child is growing dearer and dearer to its parents.

Conference of State Medical Examining and Licensing Boards.—The Preliminary Conference of the several State Medical Examining and Licensing Boards of the United States, which was held in Washington, D. C., during May, 1891, demonstrated the utility of such Conferences, and resulted, during the session of the American Medical Association last month in Detroit, in the formation of an organization for the purpose of holding Annual Conferences of the Member and ex-Members of each State Medical Examining and Licensing Board of the Union having such a Board.

The meeting in Detroit elected Dr. John H. Rauch, of Springfield, Ill., President; Dr. Wm. W. Potter of Buffalo, N. Y., Vice-President; and Dr. Hugh M. Taylor, of Richmond, Va., Secretary and Treasurer.

As stated in the constitution, the objects of this organization are to elevate the moral and mental tone of the medical profession, to divorce the medical licensing from the teaching powers, to encourage the establishment of medical examining and licensing boards, to secure harmony of action throughout the Union by the interchange of thought and experience, and to attain, as far as practicable, a uniformity of requirements for practice in the several States.

The Annual Meetings are to be held during the second day and at the place of meeting of the American Medical Association. Active and ex-members of State Medical Examining and Licensing Boards are eligible to membership. No action of the Conference is in any way binding upon the respective boards through the members who may participate in the Conference—the sole mission of the Conference being the diffusion of knowledge relative to the work of examining and licensing boards, and no Board as a board is represented or committed; but the individual active and ex-members participate in the meetings and give and receive information which will help them in their work.

Members and ex-members of examining and licensing boards who have not already connected themselves with this work are cordially invited to signify to the officers their willingness to do so. Such an organization is capable of accomplishing great good. But, in order that its mission may be carried to its highest possible end, it is necessary to have the active coöperation of many representatives from all the boards.

The Surgeon General of Illinois.—We hear and read much in these degenerate days, of the improvement and purification of the Public Service, but it has been reserved for the present Governor of Illinois to show the estimate placed upon professional ability and experience by a thorough going politician. The telegraph informs us that a young graduate of the Hahnemann class of 1887 has been appointed Surgeon General by his Excellency, Governor Fifer, to fill the vacancy caused by the death of General Matthews. The action of the Governor in selecting this inexperienced young person for so important a position is inexplicable on ordinary grounds, but in common with many others, we are of the opinion that the Governor's sincere desire to secure the "finest military medical talent" in the State for Surgeon General, will receive at the polls in November that rebuke at the hands of the profession, which such misdirected action fully warrants.

Errata.—In Dr. Billings' health report, on page 25 of The Journal of July 2, the number of guests at hotels in St. Augustine should read 16,000 instead of 1,600.

The Barnes Hospital and Medical College of St. Louis.—We are informed that the large bequest of Mr. Barnes was for the erection and endowment of a hospital, and was without provision for a college. However, a practical connection of the two institutions is designed, and it is hoped by the friends of the latter to secure all needed funds to make it a first class institution of medical learning.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 2, 1892, to July 8, 1892.

Lieut.-Col. William D. Wolverton, Asst. Medical Purveyor, will, on the expiration of his present leave of absence, proceed to Ft. Omaha, Neb, and report in person to the commanding officer of that post for temporary duty during the absence of Major Albert Hartsuff, Surgeon, on leave.

First Lieut Isaac P. Ware, Asst. Surgeon U. S. A., is relieved from duty at Ft. Douglas, Utah, and will report in person to the commanding officer at Ft. Logan, Col., for duty at that post, relieving Capt. William L. Kneedler, Asst. Surgeon U. S. A. Capt. Kneedler, on being relieved, will report in person to the commanding officer, Ft. Mason, Cal., for duty at that station, relieving Capt. Harry O. Perley. Asst. Surgeon.

Capt. Harry O. Perley, Asst. Surgeon, on being relieved from duty at Ft. Mason, Cal., will repair to Washington, D. C., and report in person to the Surgeon-General U. S. A., for duty in his office.

Capt. William Stephenson, Asst. Surgeon U. S. A, will visit the camp of the Illinois National Guard at Springfield, Ill., during the period of its encampment, commencing July 9, and ending August 21, 1892.

Capt. William H. Corbusier, Asst. Surgeon U. S. A., will proceed, at the proper time, to Island Lake, Mich., and visit the camp of the Michigan State Troops, during the period of their encampment at that place, commencing August 18, 1892.

Capt. Henry S. T. Harris, Asst. Surgeon U. S. A., leave of absence granted is further extended one month.

The next paper was entitled

RECENT INVESTIGATIONS ON THE ETIOLOGY OF DIABETES.

BY S. P. KRAMER, M.D.,
OF CINCINNATI, OHIO.

The pathogenesis of diabetes mellitus has been a fertile field for speculation. Bouchard was able to count twenty-seven theories of the disease. Nearly all of these have been based upon the classic investigations of Claude-Bernard, on the formation and excretion of sugar in the body. Since the contributions of Bouchardat, the association of diseases in the pancreas with diabetes has been frequently noted; so that Senator assumes that pathological changes in the pancreas occur in about one-half of all cases of diabetes. Baumel maintains that disease of the pancreas is found in all cases; in the milder forms microscopical, in the more severe cases, gross, pathological changes are found. This frequency precludes the possibility of accidental association. According to the view of Klebs, lesions of the cœliac plexus are the cause of this association. Either the disease is primarily in the pancreas from whence it encroaches upon the plexus, or else primary changes in the plexus give rise to circulatory and consequent degenerative changes in the pancreas.

The pancreatic origin of diabetes has been the subject of recent and very important investigations. Minkowski and Mering found that complete excision of the pancreas in dogs produced diabetes without exception. This was not an evanescent mellituria, but a true diabetes accompanied by polyuria, polydipsia, and polyphagia, loss of weight and strength, notwithstanding the excess of food given. The excretion of sugar begins immediately after the operation, reaching its highest point—5 to 10 per cent.—in from 24 to 48 hours. Aceton, acetic acid and oxy-butyric acid, are also found in the urine. The amount of sugar in the blood is also increased up to .5 per cent. The glycogen in the liver and other organs disappears to within a trace of this substance. Partial extirpation, as long as the remaining portion is not smaller than one-tenth of the entire organ, does not produce the disease. Ligation of the pancreatic duct is also without result; so that the conclusion is made that the disease is produced by the absence of some principle given off from the pancreas to the blood supply. Similar experiments in the cat and hog were followed by like results. In birds total excision of the pancreas does not produce diabetes. A confirmative case in man has also been reported. A patient of Dr. W. T. Bull died of diabetes after the excision of the pancreas. Minkowski has also given us valuable therapeutic investigations on this point. Dogs, rendered diabetic by excision of the pancreas were fed with a pancreas and pancreatic extract, without result. On successfully transplanting pieces of pancreas in the abdominal wall of dogs in whom this organ had been previously removed, the occurrence of diabetes was prevented. The subsequent removal of these transplanted pieces was followed by the occurrence of the disease. He found further that upon feeding diabetic dogs glucose, the entire amount of sugar given was excreted. When, however, lævulose was given, this did not occur, but the sugar given was used up by the organism. Minkowski's experiments have been confirmed by Hédon. Lepine and Barral have also confirmed the experiments of these authors, and from their investigations on the sugar in the blood of normal and diabetic animals, seek to advance the ideas of Minkowski and Mering a step further. They found that the blood of normal dogs when kept for one hour at a temperature of 39° C. showed a loss of from 20 to 40 per cent. of the sugar present. The greatest loss of sugar was found when the blood was kept at 39° C. This loss was found to be prevented by the previous heating to 54° C. In man a similar loss of 25 per cent. was found. Five experiments with the blood of diabetic patients showed a loss of 1.6 to 7 per cent. under like conditions. In diabetic dogs there was found a loss of about 6 per cent. The lymph of the ductus thoracicus, and the blood of the portal vein had a much greater sugar-destroying or glycolytic power than the venous blood in general.

From these experiments the authors have built up the following theory:

In the normal condition, the pancreas gives off to the blood supply a glycolytic ferment which causes a destruction of the sugar absorbed. When the pancreas is removed or diseased, this ferment is deficient and the normal destruction of sugar does not take place, but remains in the blood, and is excreted through the kidneys. They found the ferment to be chiefly contained in the white blood corpuscles. The power of the tissues to destroy sugar is ascribed to the glycolytic power of the blood.

Arthus, in repeating these experiments, found that the glycolytic power of the blood did not become manifest when coagulation was prevented by retaining the blood within the jugular vein of the horse, as in coagulation experiments. Moreover peritoneal and pleural transudates showed no glycolytic power. He concludes that glycolytic ferment is not to be found in the vessels, but is due to post-mortem changes which occur under similar conditions as attend the formation of the fibrin-ferment.

In a large series of experiments with ox blood at the chemical laboratory of the University of Cincinnati, the following was found: Both defibrinated blood and a mixture of three parts of blood and one part of a saturated solution of sodium sulphate, showed a glycolytic power. This, however, is not manifest during the first hour, is slight (10 per cent.) during the second hour, and becomes greater (20 per cent.) after four to five hours at 39° C. After twenty-four hours at 23° C. (decomposition being prevented by the addition of thymol), 75 per cent. of the sugar added to the blood had disappeared. It was found, moreover, that a temperature of 55° to 60° C. did not affect the glycolytic power of the blood. On the contrary it seemed to increase the amount of sugar discharged. Thus a loss of 14½ per cent. of the sugar added was found after an exposure to a temperature of 56° C. for one hour.

From the result of a series of experiments which will be published later, I am of the opinion that normally, a combination of the sugar and the albuminous principles in the blood takes place, in which form sugar is rendered suitable for the use of the organism. In the diabetic condition, this change does not take place.

The following may be added as a strictly true summary of the various investigations upon this subject: In the normal condition, the pancreas gives off a principle to the general blood supply by which the dextrose absorbed is so changed that its combustion by the organism is rendered possible. When the pancreas is removed, this change does not take place. The sugar is not utilized, but is excreted in the urine. The exact nature of the active principle and the change brought about by it remain a matter for further investigation.

Dr. Fell, of New York, reported a case of abscess of the liver which had come under his observation in Buffalo. In some manner the abscess was ruptured, the contents passing into the intestine. The man had diabetes before the rupture; but after the rupture the diabetes passed away. From this incident as well as from many other well known facts and the observation of other cases, he thought that we have more than the pancreas accountable for the production of diabetes and that the liver had very *important power in* this direction.

Dr. Cohen, of Pennsylvania, remarked that Lancereaux divides diabetics into the two clases, fat and lean diabetics, and confines the pancreatic form of the disease to the lean diabetics. In the fat diabetics, lesions of the pancreas have not been found. There is still another class of diabetics, namely, those which bear a close relation to the uric acid formation. It would be very unwise, therefore, to say that these theories absorbed the whole question of the etiology of diabetes. The important features of diabetes are rather the polydipsia and the polyuria, and not the mere presence of sugar. There is another form in which sugar is absent, but the polyuria and polydipsia follow a fatal course.

Dr. Kramer, in closing the discussion remarked that his theory was not a universal one, but was offered only in explanation of certain cases in which disease of the pancreas is found. These, however, are the typical cases of diabetes, attended with polyuria, polydipsia, emaciation and continuous presence of sugar. All these features are *not found in* the other classes of cases that have been referred to.

The next paper read was entitled

LA GRIPPE.

BY JOHN E. LINK, M.D.,

OF TERRE HAUTE, IND.

C. H. HUGHES, M.D., *Dear Friend:*—I have been much interested in your article, published in THE JOURNAL of February 27, 1892, on "Influenza as a Neurotic Disease."[1]

Since my first experience with the disease in the winter of 1889-90, I have regarded it as one of depression of the nerve centers, anæmia of the ultimate brain cells, as I conceive it. That the disease dates from the onset of fever and chill, or influenza, I am and ever have been seriously at a doubt. Patients marked out for such phenomena are for weeks prior to such attacks the subjects of langour and paleness of countenance. Many of the cases in this locality have almost entirely escaped fever and rigor, a few having little or no cough, all more or less suffering from neuralgia about the head or face, mostly, as they express it, a pain in the back of the head. In the majority of cases that I treated prior to December, 1891, I was enabled by the use of quinine in doses of three grains every three hours during the day, the dose to be doubled at bed-time, to keep my patients up and about at their usual avocation. The treatment had to be continued for at least two weeks; but I found that they invariably relapsed in about one month, showing again the malaise with paleness.

In May, 1891, I commenced the use of strychnia in connection with the quinine in gradually increasing doses,[2] with some benefit, as I was fully convinced but the difficulty of keeping patients up and about on continuous dosings was considerable, and in most cases they would neglect, until the paroxysm of la grippe sooner or later overtook them. Up to the time above indicated and on until the following winter, I saw no cases of serious lung involvement, as the season was mild.

I, first, in my own sickness, recognized the severe paroxysm of coughing as neurotic and bronchial. I had enjoyed most excellent health and had come to regard myself as exempt from the affects of the malady, until in December, without recognizing the cause, I found myself gradually becoming lazy with increasing desire and impulse to seek the recumbent position. I yawned frequently, a habit that I in others abominate, and tried unsuccessfully to overcome. These feelings increased towards evening and were overcome or dispelled by a glass or two of beer or light wine. I slept unusually well for me and was slow to rise in the morning. This state of affairs had lasted for a fortnight or more, when I was subjected to an unusual strain of physical exertion and exposure by being called to a small railroad station, which I reached at one o'clock at night and then took a buggy and drove through snow and sleet over heavy country roads a distance of several miles to see a poor wretch who had been stabbed in the abdomen. He lived in a miserable old log house but half chinked and daubed, no place to take rest, although I was completely exhausted and worn out. I was driven back to the station, took a freight train for home, arriving at about seven o'clock in the morning. I found business pressing so that I got little or no sleep, until one o'clock that night, when I retired. I dropped into a light sleep, but awakened in half-an-hour with a chill and an incessant desire to cough. The irritation in the larynx was so intense that it seemed nothing would give relief but the expulsion of the mucous membrane. It was more like the irritation or itching of eczema, from which I sometimes suffer, than anything else to which I can compare it. The chill continued for at least four hours. Hands and feet, in fact the whole extremity was cold, chilly sensations over the body, with the most excruciating pain in the chest, a feeling as though the flesh were being pinched and torn with blacksmith's tongs. The chill was followed by very slight fever. The severe pains disappeared with the cessation of the chill, after which the cough was slight, with small mucous expectoration streaked or colored with blood—a pinkish or strawberry juice—at no time prune-juice-expectoration. The case was at once pronounced pneumonia by several persons who saw it. To a physician I declared my non-belief in the pneumonia diagnosis. I regarded the whole phenomenon a neurosis of the pneumogastric center, both the cough and vomiting that accompanied it and continued after it subsided; the discoloration of sputa a result of extravasation from high arteriole tension from straining in excessive paroxysm in coughing, as one frequently sees in whooping cough.

---

[1] We mus [illegible] expect from such conditions innumerable phenomena [illegible] fertile harvest of physiological data for scien [illegible] observation, study, reflection, in which the [illegible] his microscopic menagerie of diminutive curiosities is not [illegible]

[2] Thirty sul-strych. parvules, 1-50 gr. three times a day, to be refilled with 1-40, 1-35, 1-30, 1-20, up to 1-16.

In my case no treatment was administered, as I was alone in my room and became unconscious after the chill left me at five o'clock in the morning. I lay upon a narrow bed and remembered but indistinctly of vomiting, first on one side of the bed and then on the other, as I happened to lie. I was too much prostrated to give an outcry and had to keep closely wrapped in an effort to keep warm.

The next day my friends found me, at about 10 A.M., in a sad plight. I lay upon my back, the ejecta from my stomach, which was simply mucus or serum, had run down on either cheek and dried, after soaking the pillow.

My treatment for the first day was hot milk, as hot as I could take it into the stomach, with large quantities of black pepper, which gave me comfort and great satisfaction. And here I will now state that I have every reason to believe that hot milk is our best stimulant in the depression from this malaise. Towards night I indulged in free and frequent doses of a strong decoction of composition powders.

At night there was a return of the bronchial irritation with paroxysmal cough, which was entirely dispelled after taking four five grain quinine capsules, at intervals of fifteen minutes. After the third, fifteen grains, I felt much relief, and after the fourth, a glow of warmth seemed to pass over my body and lower extremities, and I slept soundly, feeling quite well and a convalescent the next morning.

I remained in bed for several days most of the time. When urgent necessity demanded I would take ten grains of quinine and visit a patient. In five or six days after the paroxysm, I went to Grant Station, a distance of nine miles on the I. & St. L. R. R., and visited a patient, with no seeming bad results; though I took fifteen grains of quinine at one dose before starting, I felt none of the usual bad effects of an overdose of the drug. As soon as I returned I again went to bed. I felt then (and clinical observation has since convinced me) that the recumbent position was all that was necessary or required to rest the circulatory centers and with this, conceived there was little else to be done so far as the neurosis was concerned.

I have since sought diligently and have found no cases of true pneumonia, and I doubt extremely if such condition, can possibly obtain under the physiological conditions of la grippe—the grip phenomena. It seems to me that the physiological conditions of the vasculatory system forbid it as even a possibiliyt.

I have seen no cases of cellulitis; wounds heal slowly or refuse entirely to heal under the profound malaise.

The lung symptoms are a false pneumonia. The bronchial irritation a neurotic condition with serum poured out into the bronchioles from a relaxed condition of the vessels, as we see it in local sweating in typhoid fever, etc. So again we may have a pouring out of serous fluid into the plural cavity. This fermenting breaks down and a rotten serum is discharged on tapping, as has occurred in this locality with la grippe cases.

I would offer this suggestion, based upon my own personal experience and clinical observation; that the disease has its seat primarily in the nerve centers, principally within the medulla oblongata, the pneumogastric being the first or principal nerve involved with that of the cervical sympathetic.

This ground I took immediately after my own sickness, based upon the peculiar suffering and phenomena of neurotic or spasmodic cough and vomiting. I believed that that alone could account for the peculiar manifestation of irritation, pain and spasm, with its immediate subsidence under large doses of quinine, which I have successfully used ever since, with the substitution after twenty-four to forty-eight hours, of salicylic acid, fifteen grain doses rubbed up with acacia to a heavy emulsion, with pepsin as a stomach adjuvant and bismuth to combat the bowel complications, which I can only understand as another result of the same nervous depression. First a failure of nerve energy to do the stomach digestion, with possibly a special depression of the vaso-motor system, manifested in the pale skin with disturbed heart action, and other phenomena which I have observed, namely disturbed menstrual function. A more frequent tendency to abortion, with a decided falling off in the birth-rate as shown in the statistics of France, for 1891. All of which I think we can physiologically attribute to a fault in the sympathetic centers, having origin in the medulla and expression through the cardiac plexus and vaso-motor distribution.

There have been a few cases of cerebro-spinal meningitis reported by the local physicians here, but I have not seen them and cannot speak advisedly; but should rather look for and expect effusion as the cause of such phenomena, the result rather of a relaxed condition of the vascular tissue than from inflammatory products, or it may be as Dr. Mitchell, formerly of this city claims, that all such are neurotic and of rheumatic character. Paper published about 1870, and extensively noticed in the medical journals.

But my principal object in writing is to call attention to what I believe to be a glaring mistake on the part of the profession at large, in regard to the etiology of the disease as manifested in the lung, and that in such mistakes fatal results must necessarily result to a greater or less extent.

My course of treatment has been as above indicated, excepting within the last six months—the enjoining upon the patient of absolute rest in the recumbent position during the acute stage—if I may so designate it—for I believe, as you seem to imply in your article, that there are no sequelæ of the disease, no pneumonia, so-called, "following grip"; but the disease has not run its course, in the majority of cases, if in any, but so far as we might judge, only held in check or abatement in its violence, to be again manifested in some weaker spot under some new depressing influence.

Whether the discrasy is toxic, or an enfeebled condition from a lack of the elements necessary for the maintenance of the higher order of organic life, I do not here pretend to say. That there may be a condition of our planet, brought about by the peculiar relations with others of the solar sytem,[3] and in extended thought of imagination, the solar system with other systems, that have so changed our elements that they are poisonous—or impoverished, I do not say; but in consideration of the unusualness, as well as the universality of this discrasy, I do say that the matter is worthy of thought, and I here present it, not so much in the hope that it may possibly be in the power of man and his means of investigation to determine the facts within this possibility, as the other thing of emphasizing my views as to the trouble having its seat within the laboratory of the cells, either of the inhibitory, or force phenomena—or both.

I have had no cases of death excepting in one or two cases of very feeble old persons, where death was more the result of senile, than of grippe influence; but in a large proportion of the cases that I have had the history of, excepting in the acute lung involvement, death has occurred while the patient was in the erect position, most were sitting up, but quite a number were standing, and a few were walking around, when they suddenly, and without a struggle, died. In these the report of "cause of death" read "heart failure," *notably* Wm. Astor.

I believe that all patients will convalesce more rapidly with rest in the recumbent position, with hot milk as a stimulant and diet, than with medicine, the patient being allowed to move about.

Something of the nature of a disease can often be learned by noticing the effects of certain therapeutic agents.

There is in many of these cases a tendency to looseness of the bowels at all seasons (though neither copious nor frequent, there is a fluid condition of ferment) amounting to serious diarrhœa and dysentery during the summer and fall months.

I have been in the habit of giving sweeping cathartics—preferably castor oil, with a view to the hygienic effects, and in all cases the offensive smell of feces and quantities of gas have confirmed my belief that there was a ferment, which I can only attribute to the suppressed normal secretion and digestive process generally, but probably, I think, more especially of the stomach.

I can, too, understand why quinine and salicylic acid, especially the latter, should manifest good results in the anti-ferment rôle, in addition to its nerve influence and prophylaxis against neurotic complications. And here it seems to me is food for thought in regard to the part taken in physiological derangement through central nerve influences, as compared with the germ theory of disease now the fad of a large—too large—proportion of our investigators, and voiced by the masses.

I have had in my experience of the last eighteen months three or four cases that I think are worthy of note and consideration.

I have been in the habit for years of giving strychnia in gradually increasing doses in certain forms of nerve trouble; where the drug is indicated, I give a solution of one-half grain of strychnia to the ounce of water. Say commence with about twenty drops three times a day, to be increased one drop each day until the physiological effects are manifested in the muscles of the back of the neck, then drop back to one-half and on up as before.

Three patients that I now have in mind have persevered in this course of treatment for over one year with gradual improvement of the nervous and muscular system. One has taken as high as one hundred and ninety drops three times a day. The other two have gone as high as one hundred and eighty drops. One other continued for six months. Of the three still under treatment, not one has shown the slightest indication of the grip, either in paleness or neuralgia, and they have each assured me, that of their personal acquaintance they know of no one else that has escaped. My wife's mother is one of the number, and of a family of ten, she is the only one that has not had the disease in some one or more of its forms.

It does not seem that this can possibly be a mere coincidence, nor would one readily adopt so radical a treatment as a preventitive, but I think it should have its place as data of clinical experience in making up an opinion as to the pathology of the disease.

I think I can safely affirm that we are now more than ever before learning a most practical lesson in the value of strychnia, as it seems all observers place this drug in the very front rank in the treatment of *the depression of the so-called grip.* The value of the drug in diseases of the structures presided over by the nerves of organic life has never, I fear, been fully appreciated. For physiological data see text-books on predominance of motor-efferent-fibres over sensory.

I have seen quite a number of cases that on a casual observation caused me to seriously fear that I had a case of true pneumonia to deal with—the short catchy breathing, with flushed cheeks, etc. [In this particular I must be allowed to differ with Dr. Patton. See differential diagnosis of la grippe in article on pneumonia in JOURNAL AMERICAN MEDICAL ASSOCIATION, March 5, 1892.]

But on careful auscultation, there was something in the râles differing from those of pneumonia of the croupous or congestive form. They were more generally diffused, more or less in both lungs, and there was decidedly lacking later the characteristic dulness manifested on percussion. The sputa, if discolored, was a strawberry—not prune juice sputa, and upon the administration of 5 to 8 gr. doses of quinine every fifteen minutes, I had the satisfaction of seeing my patient turn upon the side and drop off into a natural sleep, after the third or fourth dose—the breathing full and regular, and on applying my ear to the chest, to my entire satisfaction and almost incredulous surprise, I would find that the crackling sounds had disappeared. On awaking, the patient would declare that he was entirely relieved—the phantom pneumonia a thing of the past.

Neither have those cases that I have any knowledge of had the prolonged convalescence of true pneumonia, excepting cases of abscess. I have examined quite a number that were so diagnosed, and have found in none the crippled lung of pneumonia, but one case of abscess of the lung, with cavity.

Again, death has supervened in many cases of people of note in a few hours after the attack, said to be pneumonia, if newspaper reports can be relied upon, following an attack of the grip, notably Lawrence Barrett.

---

[3] See Hicks in [illegible] Works" for April, 1892 Disturbance of the Saturnian equino[illegible] ower of Jupiter, which he states has not yet reache[illegible] years predicted disturbance of pestilence, etc.

Is it usual for patients to die of a congestive and inflammatory lung disease in a few hours? I think not.

Now, if these cases are mis-diagnosed, is it not likely that the treatment is also at fault? If it is a neurosis—neuralgia of the pneumogastric nerve, and death, as it seems to me, when occurring in the acute stage, the result of shock from severe pain, or heart failure from lack of inhibition, the case is clear that none of the ordinary remedies applicable to pneumonia would be sufficient to reach the disease or save the patient's life.

I do believe that full doses of phenacetine or antipyrine, with guarana, will have a tendency to save life by relieving, as I am sure they do, the neurotic pain; and with sedative doses of quinine and salicylic acid—first the one and then the other—will tide the patient over, or in other words, relieve the pain, and after this the recumbent position with milk diet will see the patient safe through, and with proper caution as to diet and judicious care as to over-exertion, a patched-up recovery can be relied upon.

I sometimes doubt if we will ever entirely recover our wonted vigor—sure it is that gray hairs are added to those who have passed the fiftieth milestone of life—and *they* have come to stay. And now let me suggest that if this is a neurotic disease, as I believe you have proven in your able paper, is it not well to reconsider the whole pathological field? And in recent clinical experience of this disease, as well as by analogy, do we not prove that grip is not a disease of connective or cellular tissue? Is there a cellulitis resulting in abscess? does it produce abscess? Is the congestion engorgement of the vessels with swelling or abscess? or is it like neuralgia and kindred diseases, a non-congestive disease, a neurosis in every sense of the word? Inflammatory rheumatism is an inflammatory neurosis, but the same condition existing in the lung would not be a pneumonia. So of la grippe influenza, its pathology is of an entirely different character from the condition of the tissues of the lung recognized as pneumonia proper.

I have frequently been called to act in a surgical capacity, where abscess with periosteal involvement existed as the result of cases diagnosed inflammatory rheumatism, but I never recognized the diagnosis as correct. Neither can I with consistency accept an involvement of the lung in an inflammatory neurosis as pneumonia, neither can I understand from my personal observation, clinically, how there can be coagulated lymph deposit from a neurotic inflammation, such as we see and recognize as la grippe; but we can have an outpouring of serum from relaxed tissue, as manifested in local sweating and in the watering of the eyes from intense neuralgic pain, and from such phenomena I can understand how there might be an infiltration into the pleural cavity and into the bronchioles of some part of the lungs, causing circumscribed dulness and resulting in abscess through mechanical pressure and paralysis, as witnessed (in a more extended phenomenon) a few days since in the corpse of a young man who had died but a few minutes before, sitting up in his chair, where I found him. In this instance it seemed clear to my method of reasoning that death was the immediate result from asphyxia, the lung being flooded with its own serous extravasation. Laennec taught that pulmonary œdema may occur as a primary condition causing suffocative orthopnœa, but whilst this case was one of clear orthopnœa—the patient having risen upon the feet and even made efforts of jumping from the floor, crying out "I feel so strangely, I am smothering"—yet I believe there are conditions here brought about by a loss of power within the pneumogastric nerve so nearly approaching total paralysis—not quite equal to the severance of the nerve, in which sero-sanguineous fluid infiltrates the tissues—but so near it as to dilate the vascular system, allowing only the pure serum or water of the blood to filter through. When he was laid upon a lounge, the clear serum first bubbled from his nostrils, then with the effort of resuscitation, in pressing upon his chest, it came in gushes from both of the nostrils, until at least two quarts were discharged before I left him, and still it continued, if considerable force was used in pressing well down upon the sternum. This man "had had the grip," had not been confined to his bed, but had been up and around, though "as pale as death," as expressed by one of the family.

This is the grip and not a sequence of it. It is the disease, unrecognized and neglected, I fear, by the profession which the people rely upon for advice in sickness and for the prolongation of life, and whilst I am no writer and slow to put myself in print, this thought has pressed upon me until I am constrained to give it utterance through a medium that I believe capable of giving the matter that consideration which its importance merits. Therefore I lay it before you to judge of its merits, and give it such notice as in your judgment you think best.

Since writing the above I have had two cases of note. One in corroboration of the lung theory advanced above, in the person of a little girl 9 years old. The whole family, with the exception of the mother, had suffered more or less from the grip, this child being the last to take down. She has a history of what they call "tisic" since she was a baby. She has shown lung trouble whenever she contracted a cold. The cough was a marked symptom for two or three days of her sickness prior to the time I saw her. She had taken quinine in moderate doses, until at the time I was called the stomach had rejected it. I ordered a mixture composed of antipyrine, 25 grs. to the oz. each of elixir of guarana and paregoric, to be given in teaspoonful doses, in a mistake, I thinking there was twice the amount of antipyrine to the dose in the quantity given. The patient continued in a condition to create alarm on the part of the family, so that I was again sent for. I found the breathing catchy, about 60 to the minute, the countenance pale, with a flush on either cheek. She lay prone upon her back, as in such cases with extreme exhaustion. There were crepitant râles over the whole aspect of both lungs, but no dulness in any part on percussion. I doubled the dose of medicine as above given, and left the house for half an hour to visit a patient in the neighborhood. When I came back, there was evidence of marked change in the improvement of the symptoms. I repeated the dose, and in less than one hour from the time of taking the first dose, she had turned on the left side and was in a healthy sleep, such as she had not before enjoyed for two days and nights. The breathing was full, easy and regular, with scarcely a bronchial râle to be detected, and she is now, two days later, comparatively well, with no pneumonia or other lung symptoms. Salicylic acid in 8-gr. doses was substituted for the quinine, but the restoring influence seemed to be from the anti-neurotic effects of the antipyrine, combined with the stimulant and anodyne effects of guarana and paregoric.

The other case (as showing the pneumogastric involvement with its expression upon the heart, with possibly an involvement, also, of the sympathetic fibers entering into the cardiac plexus, all having their origin in the medulla), was that of a passenger conductor on the Vandalia system, running out from here to Indianapolis and return, both ways about 146 miles.

He had suffered for a year or more with the grip in mild form. He was a neurotic subject, all of his brothers having died of consumption. His mother had eczema all her life. His height is about 5 ft. 11 in., and his weight 120 lbs.

At about 1 o'clock at night he awakened his wife and son, telling them that he thought he was dying. He was somewhat confused and made some effort to move about, but was prevailed upon to keep quiet. He said the trouble was about his heart. I was called and reached the house about 1:30. I found a fluttering pulse-beat, which after repeated effort I was enabled to count by tens, his son holding the watch. I made out in two successful efforts 200 beats in fifty-seven seconds. I gave him at once 10 grs. of quinine and a mixture of antipyrine 7 grs., 2 drachms of elixir of guarana and a tablespoonful of paregoric. In thirty minutes the patient began to realize a sense of relief, and the pulse-rate had perceptibly diminished frequency with increased volume. The dose as last described was repeated, and in half an hour the pulse was still further improved to 140, with good wave. The patient dropped off into a natural sleep. I visited the house at 11 o'clock the next morning, and was informed that with some difficulty my patient had been prevailed upon to give up his run at 7 A.M., and was then up town on business. He returned whilst I was still at the house. His pulse was 116 and he declared he felt quite well, only a little weak. After resting half an hour, the pulse dropped to 96. I took the pulse two weeks later, 86—and he is constantly on duty, running 146 miles a day, as passenger conductor on Indianapolis train.

I believe the only remedies in all such cases are those applicable to neuralgia—sedative doses of quinine and salicylic acid, as above indicated, when the urgency of the case does not call for more prompt relief, as in the last cases. Antipyrine with guarana has been my preference, for the relief of pain and other discomforts neurotic in character; though with a limited experience, with phenacetine, I believe as good results might be obtained.

The prejudice existing against antipyrine has, so far as my personal experience goes, no foundation in fact. With the combination of antipyrine and elixir of guarana, I have no hesitancy in increasing the dose all the way from 8 grs. up until the desired result is obtained. I have had just as gratifying results with the remedy where there was the depressed or diminished heart's action, with pain and paleness, as in the increased with pyrexia.

I would propound numerous questions to the profession, but when I come to select, I find that one so intimately involves another, which with the necessity of elaboration to make each one intelligible in its bearings, I find it only possible here to give a few points in elaboration. But first, if the disease now prevailing is not one of neurosis, or from anæmia-starvation, or depression of the central nerve cells, why is this stage of paleness precedent to the expression of either influenza or la grippe? The former a catarrh of the air passages of respiration, the latter the expression of neuralgic pains in different parts of the body, possibly more frequently the chest. If this is true, as I have observed, that paleness precedes such attacks, is it proper to designate the other expressions, as those of pneumonia, falling out of the hair, diseases of the alimentary canal, the reopening of old syphilitis, neurosis, etc., *ad infinitum*, as sequelæ of la grippe, or are they part of the phenomena of the disease or state of central depression, and the influenza and la grippe, one and a part in common with the others indicated? My cases of dysentery of last summer, when an epidemic raged here, were all treated with grip remedies (with little variation from that used in the lung influenza) suggested by the characteristic paleness of countenance and tongue, with the neuralgic pain in the back of the head. Some of them "had had the grip," as they expressed it. All yielded readily to the salicylic acid treatment in combination with subnitrate of bismuth, with the pepsin which I always find best to combine with the large doses of salicylic acid, as stated above. If this paleness with malaise does precede the attacks of influenza, is it logical to assume that the other phenomena of inflammatory neurosis are sequelæ of the grip? It seems to me that we are here taking effect for cause, and that la grippe *per se*, is only one expression of a cause first manifesting itself in the brain cells, especially the medulla oblongata, the seat of the pneumogastric and vaso-motor, with possibly—in fact most probably—some of the centers in the cord. I do not believe that the disease is one of pyrexia, neither psychosis, influenza, neuralgia or myalgia. The only symptom that I can conceive as characterizing the prevailing epidemic is that of paleness of the countenance, with a peculiar whiteness of the tongue, which is not in the early stage coated or furred, but has the appearance of having been soaked in milk—the surface in its whiteness suggesting to my mind that comparison.

That alone can account, it seems to me, for the "babble" of confusion expressed in the literature of our journals from various sources of authority, of men in high places. One will speak of pneumonia following grip, another of the differential diagnosis of la grippe and pneumonia, œdema of the lungs, pulmonary congestion and hypostatic congestion, etc. [See for latter an article in THE JOURNAL, Chicago, March 5, 1892.]

In conclusion, for I am now far beyond my intended limit in the letter, or paper, as you please:

I place the seat of the disease principally in the medulla, with its first expression in the sympathetic nervous system, as manifested in paleness; next a neurotic condition of the pneumogastric, as manifested in coughing, vomiting and pain, with later possibly an extension to the spinal cord, manifested in neuralgia, myalgia, etc. The psychosis may be only an expression through feeble or depressed vital force, exciting or inducing to insanity those formerly so affected or predisposed, in the same way as eczema, syphilitis, etc., returned.

Since commencing this article as an open letter to my friend Dr. Hughes, I have elaborated, as clinical experience and research into the journalistic literature of the subject have given data, until the present, having no cause to change, but much grounds for adding to until the time, first, of presenting it to the Vigo County Medical Society for criticism, and since its reference to this body, I have been somewhat at a loss to formulate my opinion so as to give to the disease a comprehensive designation.

It seems to me that the epidemic now prevailing can be designated by no better name than an epidemic malaise, manifesting itself in various neuroses, each differing from the other as controlled by climate or season, individual weakness and predisposition. Adding to what I have before written as to its non-specific character of influenza—catarrh, nor la grippe, sudden seizure, neuralgia and myalgia, neither psychosic nor pyrosic; but that individual cases may go on to the fatal termination of heart failure or pneumo-hydrix (name coined for want of a better, meaning water or serum within the air cells or bronchioles) cited; and what has been claimed as "the depression following grip," without the previously recognized manifestation called grip: I wish to call your attention to an editorial in THE JOURNAL, Chicago, of April 9, 1892, which I think has a strong bearing upon the subject, but falls short in its range of comprehensiveness. The writer, after referring to the sad fate of an eminent writer and teacher of our guild, speaks of the necessity of a spring vacation, based upon the fact, as stated, that doctors for the last two or three years do not stand the winter's work as formerly, says: "Malaise and a propensity to lassitude indicate that many a hard-worked physician may be under the epidemic influenza without being *sick* (italics are mine) enough to give up work."

It occurs to my mind here that a like thought and interest on the part of doctors would show them that others, as well as his brother, were entitled to and need the same consideration; that though not sick with pain and fever they, too, need rest or treatment, if not both—else, as in the instance of the eminent brother referred to, "the doors of the insane asylum—or the coffin lid—will close upon them."

This was followed by a paper on

A MODIFIED FORM OF CONTINUED FEVER FOLLOWING THE EPIDEMIC LA GRIPPE.

BY JOHN H. HOLLISTER, M.D.,

CLINICAL PROFESSOR OF MEDICINE, CHICAGO, ILL.

The remarkable epidemic of influenza which appeared on the confines of Russia in the autumn of 1889, and which during the following winter spread over nearly the entire area of the two Continents and which, in like manner and with even more fatal results re-appeared in the winter and spring months of 1890 and 1891, was conspicuous for the rapidity with which it traversed the two hemispheres, for the added intensity which it gave to our ordinary diseases and for the profound and prolonged prostration of those of its subjects who survived its fatal effects. Its differential diagnosis was the more difficult, by reason of its simulation of the ordinary symptoms of our endemic diseases. The numbers of our people that were affected, the unusal severity of their sicknesses and the alarming fatality which resulted therefrom, was proof beyond question that this epidemic was exerting a most profound influence upon every form of disease which we were called to treat, but by what agency or in what manner such result was accomplished, the most astute and scientific of observers were unable to determine.

It will not be the purpose of this paper to discuss either the etiology or the pathology of this disease only in so far as it shall be necessary to trace its influence in the modification of our ordinary diseases and possibly in paving the way for the appearance of some forms not hitherto observed.

Doubtless every physician whom I have the honor of addressing has had abundant opportunity of studying this disease at the bedside and has had occasion to note its exceedingly diverse manifestations, in connection with various forms of affection in different patients.

A sense of profound prostration was the universal complaint, whatever the form of disease. The nervous system seemed to bear the brunt of attack and such was the effect upon the vaso-motor system that the vascular organs, when involved, seemed the more imperiled. By reason of the frequency of severe catarrhal symptoms, it was from the first termed influenza, but while the respiratory organs were most frequently involved and with a larger fatality resulting therefrom, still each of the more vascular structures, as for example, the intestinal mucous membrane, the liver and the spleen, were apt to be affected and with a severity of symptoms not common at other times. Its depressing influences told severely upon our aged people and multitudes of these were borne down from simple physical exhaustion. The loss of muscular power was a common complaint and numbers died from the affection termed heart-failure.

Nervous prostration was a household expression and unhappily it was, by no means, a creature of the imagination. Mental vigor was often times greatly impaired. Men in responsible positions were obliged to lay down their business by reason of the failure of their mental powers, professional men were especially prone to suffer in this respect and while slowly recovering, they were for long periods of time conscious of an inability to grapple with their professional duties as before time.

Mental depressions and despondencies were characteristic of this disease. Insanity was of more frequent occurrence and even suicides became more common. An added intensity seemed to be imparted to every form of disease and directly or indirectly from its influence upon the masses of the people such an increased death rate was achieved as has been equalled in no other epidemic, cholera not excepted. Some specific cause must be responsible for such a wide spread epidemic and for such results. Suspicions point to atmospheric and telluric influences and again to the undiscovered microbe, but as yet the specific cause remains unknown.

Now that this wonderfully pervasive epidemic has disappeared, it concerns us all to know to what extent if any, it shall exert a modifying influence upon our ordinary diseases and whether in its pathway new forms of affections shall arise.

While men are every where studying the former of these questions I will venture to discuss with you the latter, by bringing to your attention a form of continued fever which fell under my observation and which for a period of time was widely prevalent in Chicago. In that city, during the months of

February, March and April, 1891, the epidemic termed la grippe had been remarkably prevalent and with a fatality before or since unparalleled. A comparision of the death rate during these months, with the corresponding months in other years, after making due allowance for the increase in population, will serve my purpose best: In February 1889, the death rate was 15.50 per 1,000; in February 1890, the first year of the epidemic, it was 22.03 per 1,000; in February, 1891, 19.24; in 1892, 21.84. In March, 1889, the rate per 1,000 was 18.22; in March 1890, 12.52; in March 1891, 34.05; in 1892, 20.43. In April 1889, the death rate was 16.72 per 1,000; in April 1890, 17.46; in 1891, 34.50; 1892, 20.19. In May of this year the epidemic had gradually disappeared and the death rate had fallen to less than 19 in 1,000. It was during this month that a form of continued fever became very prevalent in Chicago. It did not seem confined to particular localities, nor classes, nor conditions of people. Almost, if not all our practicing physicians, were called to meet it frequently in private practice and the fever wards of all our hospitals were crowded to their utmost capacity. The cause of this so prevalent disease could be traced to no common source, either of water polution, defective sewerage or any other known causes of contagion. It was thus prevalent during the months of May, June and July of that year and immediately succeeded the three months of severest visitation of la grippe. It had well nigh disappeared in the following August, and thus far there has been *no* reappearance. At the date when this form of fever began to be prevalent I not only met it often in private practice and in consultation with other physicians, but being then on duty in one of our largest city hospitals, my attention was at once called to the crowded condition of our fever wards and to the unusual number of cases which were registered typhoid fever. I soon began to notice a very striking resemblance one with another, in a large number of these cases, so that the history card of the one might be easily duplicated with many an other one with only slight variations. I also began to observe that while in some important features these cases resembled those of typhoid fever, yet in many other respects the symptoms were essentially different. From a much larger number of hospital cases at my command I have selected the history cards and records of fifty well defined cases and after a careful comparison of these am able to give the following as an average portraiture of the disease. I may presume a general description by saying that neither the previous history, nor occupation seemed to throw light upon the exciting cause, for while some had just previously suffered from la grippe, an equal or larger number had not been sick until now.

The prodrome was apparent for from one to five days, with special complaint of extreme muscular soreness and general prostration. The onset of the fever was usually gradual and without chills. It was *continuous* and so uniformly without intermission that by common consent it was everywhere termed typhoid fever. The average duration of the disease or the time that the patient was confined to the bed in the cases here cited was 23¼ days.

Early in the history of each case a high range of temperature was attained and this was maintained in a remarkable manner during the entire course and until convalescence was fairly well established. There was usually only a moderate demand for drinks, food was repulsive and rapid emaciation ensued. In giving reports of *pulse, respiration* and *temperature*, these averages for sake of brevity are taken in periods of five days each. For the first five days the average morning temperature, dating from the term of attack was 101.3, pulse 92, respiration 32. The evening record for the same days, 102.8, pulse 101, respiration 38. During the second period of five days the morning average was 102.1, pulse 113, respiration 39. During the evenings of the same days 103.4, pulse 118, respiration 39.6. During the third period of five days it was difficult to make satisfactory averages, since in some instances the temperature became nearly normal, in others it remained at a high range until convalescence had been well established, but in other instances, by reason of indiscretion in eating or from other causes severe relapses had occurred. It will be observed that the frequency of the pulse was almost never in proportion to the range of temperature and this was also true of respirations. Referring to the conditions of the nervous system I may briefly state the fact that aside from a sense of prostration the nervous symptoms were by no means as severe as is usual in ordinary cases of typhoid fever. The cerebral organs and the nervous centers generally were rarely severely involved. Pain in the head was not a usual matter of complaint. The intellectual faculties were rarely disturbed, there was neither delirium, coma nor subsultus, even in the more severe cases. The secretory action of the skin, mucous membranes, liver and kidneys was notably diminished, and the resumption of their normal functions was unaccompanied with what are termed "critical discharges." It should be said with reference to these cases, that in four instances for the first ten days proper and continuous perspirations rendered them exceptions to the rule. The organs of digestion were matters of continuous observation and study in these cases and in these were found the most marked variations from the symptoms usually observable in typhoid fever.

The mucous membrane of the mouth was intensely *red*, but the secretion of the sublingual glands was such that the mouth was seldom dry and parched and sordes were not found upon the lips and teeth. The tongue had always a bright *red* appearance and in almost every instance even to a marked degree, spear pointed. It had never a dry brown coating nor glazed center, nor fissures, usually rather moist at the edges, the dorsum of the tongue being almost always covered with a clean *white* coating, as white as though it had been smeared heavily with a coat of white paint; and appearing thus for many days.

As a rule there was an entire loss of appetite and emaciation was rapid. The demand for drinks was only moderate, vomiting rarely occurred and pain in the epigastrium was seldom a matter of complaint.

The bowels were not tympanitic nor tender upon pressure; in none of the cases was peritonitis developed. In nearly every case during the entire course of the fever, the bowels remained constipated, usually requiring laxative medicines and enemas to secure their proper action. In only three instances did the alvine evacuations resemble those usually found in typhoid fever. In each of these cases the discharges were carefully examined by competent expert, but in neither of them was the typhoid bacillus discovered. In fact in these fifty cases there was an absence of those symptoms which usually so clearly indicate the presence of abdominal lesions, in the great majority of cases of typhoid fever. The kidneys did not seemed to be involved in this disease. The urine had the appearances which are usually present in continued fever, with occasional sedimentary deposits of uric and phosphatic salts and contained neither albumen, casts, blood, pus corpuscles, nor sugar, and only in a few instances a small amount of bile. There was a noticeable tendency to relapses in the later stages of this disease but in almost every instance where there was a sudden return of high temperature it seemed attributable to an indiscretion in diet. Watchful as the interne and nurses might be, as the appetites of convalescing patients became clamorous, supplies of fruits and of indigestible food were sometimes stealthily obtained and almost always, an added week or more of severe relapses was the penalty which was paid.

I will not presume to consume your valuable time, by any extended narrative of the treatment of these cases. The characteristic feature, more than any other which obtained during nearly the entire course was that of excessive temperatures. In this connection I wish to state that much less satisfaction than we had anticipated was found in the use of either mild or heroic doses of the recently introduced *antipyretics*. Our main reliance for reduction of temperature came to be upon the frequent repetitions of spongings and sheet and towel packings with the liberal use of moderately cold water. Convalescence was more rapid than is usual in typhoid fever, and intercurrent affections of any importance were rarely developed, although a sense of debility remained for long periods of time. Only three of the cases here cited proved fatal, one from pneumonia developed in the third week of the fever, and two from physical exhaustion without any apparent local lesion; neither of the fatal cases seemed to suffer from intestinal lesion. Except in the case of pneumonia the post-mortem examination failed to reveal any special local lesions.

The fact that this fever was so generally prevalent in our city as to be regarded as another epidemic, the fact that it was usually designated as typhoid fever, both in hospital and in private practice,that it so closely followed in the wake of la grippe, and the further facts which I have detailed which seemed to render it *distinct from* typhoid fever, have been my warrant for presenting this subject at this time and for seeking the judgment of the profession as to whether it is to be classed with ordinary continued fever; whether it should be termed typhoid; or whether, and as I believe, it was developed by some unknown cause, perhaps modified by the epidemic of la grippe, presenting, in fact, a *new form of continued fever.* The surrounding conditions of these patients were the same as in other years, yet with an experience, in that hospital, which dates over twenty-five years I had not had a like experience in the observation and study of *fever*. The epidemic, if I may so term it, disappeared almost as promptly as it came and though from that time to this our environments have been the same, yet up to this date there has been no re-appearance of this disease. Without presuming to suggest its *cause* nor to explain its pathology I have ventured to consider it as a distinct form of continued fever, following closely upon the subsidence of *la grippe*.

Dr. Didama, of New York, asked the last speaker whether the color test of the urine had been found in his cases; also, what was the character of the *tongue*; whether these and other characteristic signs of typhoid fever were present or absent in the cases which he had reported.

Dr. Hollister replied that the color test was not made, but that the appearances were similar to those in typhoid fever. The diet he had employed was of milk and pre-digested foods. There was an absence of the eruption and there was marked pallor, except here and there a spotted condition. There was the absence in these selected cases of petechial spots. The speaker had selected fifty cases which had given him symptoms most unlike those of typhoid fever.

The next speaker agreed with Dr. Link, on the neurotic origin of the disease. He had been in the habit of describing la grippe as affecting the nervous system, or the lungs, or the stomach and bowels. In nine cases out of ten it commences with vomiting rather than with diarrhœa, as is usually the case in enteric fever. His treatment of typhoid fever was the old hydrochloric acid treatment; but the grippe, he treated as though it were a neurosis. The difference in the treatment was striking, but the difference in the duration of the disease was also striking. I think, he said, that there is a distinctly neurotic type of the disease, of which we had a great deal in 1889, a pulmonary form, affecting the pneumogastric and the fifth pair of nerves, and a gastro-intestinal form affecting the pneumogastric and vagus.

Dr. Eckles, of Iowa,thought that if Dr. Link's premises had been correct the conclusions would have been correctly drawn, but the error lies in the fact that his premises are wrong. Therefore, his conclusions are also incorrect. He then entered into a discussion of the various kinds of nerves and concluded that the influenza was not likely to attack a nerve consisting of mixed elements like those of the pneumogastric. He thought the symptoms observed in each and every case of influenza physiologically contrary to what we would expect from a "nervous depression" of the pneumogastric nerve.

Dr. Hemingway, of Illinois, could not agree with Dr. Link or the last speaker as to the origin of la grippe. He did not think that the disease was primarily of nervous origin, but that this nervous disturbance was the result of some toxicity. If we had only the nervous origin, how could we account for such influences as the weakening of the heart due to fatty degeneration? The mildest attack may be followed by heart-failure and death. The only reasonable explanation which we have for the phemonena is that the poison, whatever it be, whether a ptomaine or something else, affects the heart in a way to produce fatty degeneration and atrophy.

In regard to the fever spoken of by Dr. Hollister, it seemed to the speaker that we have here the evidence of some ptomaine working. He had observed that in this disease, if he saw the patient early and administered a good dose of calomel he did not as a rule have to see the case a second time. He had seen more cases but once than he had seen five or six times during the epidemic. On the contrary, he had found that where quinine, antipyrine, antifebrine, etc., had been given, he had to see the patient often. The most obstinate and most prolonged cases were those in which acetanilide had been given. Opium does have a curative effect, but the mercurials of some form stimulate the glandular system so as to counteract the production of ptomaines and are far more efficient than any other.

Dr. N. S. Davis, Jr., of Chicago, remarked that the most persistent symptoms in la grippe are the result of toxic agents, and that the disease may be regarded as a neurosis in the majority of cases. Unfortunately in many cases there are symptoms associated with the nasal and other mucous membranes producing the effects that have been referred to as nasal, gastro-intestinal catarrhs, etc. In one epidemic these symptoms prevailed to but slight degree. Another fact which had not been brought out during the discussion, had impressed the speaker as an important peculiarity during the subsequent epidemics, was the contagiousness of the disease. He could not help thinking that it was contagious on account of the great frequency with which it attacked large numbers in the same family, the same factory or house. It occurred much more frequently in those working in doors than it did in those out of doors.

Dr. Herrick, of Cleveland, agreed with the last speaker as to the contagiousness of la grippe. He had observed it in himself and other physicians attending large numbers of those affected with it.

Dr. Kennedy, of New York, asked whether immunity was conferred by one attack.

The question was promptly answered in the negative. The Section then adjourned until 9 o'clock June 8.

SECOND DAY—WEDNESDAY, JUNE 8.—MORNING SESSION.

The first paper of the morning was

POSITIVE AND NEGATIVE RESULTS OF MEDICAL ACTION.

BY BEDFORD BROWN, M.D.,
OF ALEXANDRIA, VA.
EX-PRESIDENT OF THE MEDICAL SOCIETY OF VIRGINIA, MEMBER OF THE MEDICAL EXAMINING BOARD OF VIRGINIA, MEMBER OF SOUTHERN SURGICAL AND GYNECOLOGICAL ASSOCIATION, AND OF THE AMERICAN MEDICAL ASSOCIATION.

I have long been impressed with the importance of studying and clearly comprehending in the application of our therapeutic agents, the positive or negative, the certain or uncertain action of our remedies. It may be said now that this is a question duly considered by every intelligent physician. I think that I can demonstrate to you during the course of this paper that this question, even at the hands of intelligent, competent physicians, does not always receive the consideration that it merits.

This question of the positive and negative results of medical action is eminently a practical one. The more closely one may calculate upon and approach certainty of results in medical action the better will be our results in the treatment of disease.

On the contrary, the less attention we pay this important question, the less weight we attach to the character and action of our remedies, the more unfavorable will be the results of our practice.

In summing up an aggregate of the fatal cases in practice we will find that a certain proportion is due to the incompetency of the physician, incorrectness of diagnosis and ignorance of appropriate therapeusis; another proportion from the incurable character of disease, and another still from carelessness of physician and nurse.

But, notwithstanding our diagnosis may be correct, and our therapeusis proper, and we may be entirely competent to treat disease, our success in its treatment may be signally defeated and the results of our medication may be absolutely negative, because of the manner in which our prescriptions are compounded: because of the adulteration in the manufacture of drugs or the substitution of cheap and inferior preparations for those of a standard quality and value.

In these may be found some of the principal causes of the negative results of medical action and of the uncertainties of medicine. A single dose of a worthless, inert, impure, adulterated or insoluble or inferior substituted medicine may cost the patient his life, and the attending physician his reputation. The reputation of the physician is his capital, and that capital is acquired alone by his success in practice. In the acquisition and preservation of the capital it behooves him, like the banker or merchant, to look to the details of practice and to know more than the certain and positive actions of his remedies. If he finds his cases retrograding in progress, there is surely an error somewhere, either in his diagnosis, in the selection of his remedies, in the nursing, or in the character of those remedies, or in the method by which they are prepared. In the administration of therapeutic agents their action must be either positive or negative, and the results either good or bad.

In treating of the subject of negative medication, one of the first and most important questions for consideration is the solubility or insolubility of medicines in the human stomach.

The pill is probably the pharmaceutical preparation in most general use, and of all others is the most liable to be prepared in an insoluble manner. No one can well over-estimate the importance of the simple question of the solubility or insolubility of the *pill* in the practice of medicine, in the results of treating disease. There can be no doubt that a very considerable proportion of the medicines prescribed in the form of the pill are absolutely insoluble in the human stomach. And so far as any remedial action is concerned they as well might have been dispensed with. Of course, such medicines can exert no influence one way or the other, for good or evil, on the progress of the case, whether it terminates fatally or not.

In regard to the use of insoluble pills and capsules in treating disease, my attention was called to this subject some twelve years since in a most positive, but unpleasant manner, and I cannot impress the subject upon the attention of the audience better than by relating a history of the circumstances.

I had under my care a very bright and interesting boy of fourteen, with a most violent form of adynamic malarial fever. I was prescribing twenty grains of quinine per day in divided doses, in what was intended to be fresh pill form.

Instead of fresh pills, the druggist had, as I discovered only too late, been dispensing sugar coated stale pills. The temperature of my patient, most unaccountably to me, notwithstanding the regular administration of this quantity of quinine, was daily increasing. I increased the quantity to thirty grains per day and obtained no better results. On the contrary, the temperature rose to 105° accompanied with delirium, great prostration and dry tongue. In addition I used other antipyretics and frequent cold sponging. Very suddenly the temperature leaped up to 106°, and as the child was then suffering much from diarrhœa I asked to see the alvine discharge. In the discharge examined I discovered two or three small white balls. They were washed and examined, and found to be sugar coated quinine pills perfectly undissolved. The mother informed me that she had observed those lumps, as she termed them, in all the discharges when examined, but supposed they were peculiar to the disease. There was an explanation of my patient's steady and downward progress. Probably not a pill had been dissolved in the stomach and not a grain of quinine had been absorbed into the system. My patient was lost, not from incorrect diagnosis, not from the prescription of improper medicine, not from careless or ignorant nursing, but from the use of an insoluble pill. Subsequently to this I was attending an interesting little girl of twelve, with malarial fever. I observed at my daily visits that the condition of my patient was growing worse, notwithstanding she was then taking twenty grains of quinine per day in pill form. I had ordered from the druggist some freshly prepared quinine pills. The temperature of my patient now rose to 104½° on the border lines of danger. At this stage, as the child was suffering from diarrhœa, I inspected the discharge and found two undissolved pills. On inquiry the mother informed me that she had observed them in almost every discharge, but supposed them to be peculiar to the disease. I called on the druggist in person and found that he had been dispensing throughout the case sugar coated pills. I then ordered fresh pills to be made, but unfortunately they were compounded with gum arabic, and the next day they were also found in the alvine discharges in an undissolved condition.

I now prescribed twenty grains of quinine in solution per day, and in twenty-four hours the condition of my patient was better, and her subsequent progress was uninterrupted. The only excipient I have found that would render a pill perfectly soluble in all grave forms of fever, is pure *honey*. Gum arabic, gum tragacanth, even sugar will render a pill insoluble in these conditions.

In the grave and malignant forms of fever the functions of digestion are reduced to a minimum, and the capacity to dissolve either food or medicine is diminished to the lowest degree.

To a digestion impaired to this degree we must be careful to adapt the solubility of our medicine. To patients with these grave forms of disease, I order only pills freshly prepared with simple honey or glycerine. I have inspected the discharges of patients repeatedly when taking pills prepared in this manner, and never found one undissolved.

Indeed, in the grave types of fever of all descriptions where certain organic changes of the mucous membrane of the alimentary canal have taken place, rendering them incapable of performing their proper functions, and the great sympathetic system is partially paralyzed for the time, they are not in a condition to dissolve a pill in any form, and then medicine in solution can be given, and I prefer quinine in a solution of muriatic acid. In this condition of affairs to give an insoluble pill is to permit your patient to die. When the temperature of our patient reaches 104°, his condition is growing serious and he needs medicine in a form that will act promptly and speedily. When it rises to 105° he is on the border lines of danger, and when 106° is attained I trust not medicine in pill form, as a stomach at a temperature of 106° will hardly dissolve a pill twelve hours old sufficiently rapid to meet so grave an emergency. Then the antipyretics must be given either in solution or powder. I feel satisfied from my own personal experience that a certain proportion of human lives have been sacrificed from neglect of this principal alone.

In these alarming conditions we cannot trust the lives of our patients to the uncertain chances of the solubility of a stale sugar or gelatine coated pill or capsule.

I have on repeated occasions when the temperature had reached dangerous limits, and the alimentary canal was incapable of dissolving a pill, and rejected a solution of quinine, given, by enema in mucilage, that article in thirty grain doses with the happiest effect.

During an epidemic of grave malarial fever I had a case of specially malignant type with a temperature of 106° that had been taking twenty-five or thirty grains of quinine without effect in pill form. I ordered an enema containing forty grains of quinine in a gill of milk and thirty drops of tincture of opium. The temperature fell to 103° in twelve hours, and then in twelve hours more to 101° on repetition of the enema. These details would seem to be of small importance, but in the treatment of disease they are of practical worth.

There is a question that arises now whether the cool bath in very high temperature does not aid the digestive organs in dissolving both medicine and food. I believe that it does promote that object. The hurry and bustle of the age, the desire to economize time and labor, and the thirst for gain are responsible for much of the delinquencies of both manufacturers and druggists. For the past twenty years the country has been flooded with sugar and gelatine coated pills and capsules that are kept and dispensed in a stale and too often insoluble condition to fill prescriptions for the very gravest as well as the mildest cases. It behooves us to look well to the solubility of our remedies given in all grave forms of disease as typhoid or malarial fever, pneumonia, dysentery, cholera morbus, diarrhœa and in all other cases where the vital condition is reduced to a low standard, or we may surely expect to obtain negative medication and unfortunate results. For the purpose of illustrating more clearly the important principle involved in this question, I think it proper to recur again to the relative capacity of the digestive organs in disease to dissolve solid substances. For instance, I have known a hard stale pill to remain in the stomach for twenty-four hours and then be rejected in an undissolved state. I have known a portion of crust of bread to remain fifteen hours and then to be rejected without having undergone digestion. I have known in the case of a child a portion of green apple to remain twenty hours undigested after being swallowed, and then rejected by an emetic. I have seen a hard portion of fruit cake to remain in the stomach undigested for nearly twenty hours, and then came convulsions that were relieved by its final rejection. Even in transient conditions of indigestion the capacity to dissolve solid substances is greatly reduced. To recur again to the question of the solubility of the pill, while it is true that a perfectly healthy stomach and vigorous digestion might dissolve even the stalest sugar or gelatine coated pill, in a large proportion of cases they would pass through an entire alimentary canal in a state of disease, with its vital standard reduced, and our object would be defeated and the result of our medication would be *nil*. In the prescription and administration of medicine and food in grave forms of disease how few of us take into consideration the lowered standard or capacity of the stomach to dissolve ingesta. But there are various other agencies of equal importance by which we can derive negative results in the application of our remedies.

The criminal adulteration of drugs by dishonest manufacturers is another means not less important and more reprehensible. For this our profession is, in part, to blame, as they too often encourage obscure, unscientific, dishonest manufacturers, simply because their productions are cheaper. The laity is always captivated by cheap drugs. To them the opportunity to purchase cheap medicine is that much saved. They are prone to regard cheap medicine in the light of a bargain as they would cheap groceries or cheap dry goods. This crime of adulteration of drugs might be in a measure, if not wholly, corrected if medical men and patients would patronize alone honest, skilled manufacturers and druggists.

There is a popular delusion that cheap druggists and cheap drugs, like cheap groceries and cheap clothing, are profitable things to patronize. The profession should in every manner possible endeavor to correct this delusion. This is the cause of an infinite amount of injury in defeating positive and certain medication.

Pure drugs always command a standard value and no pure drug can be sold for less than the standard price without loss. Hence, the very fact that drugs are sold cheap is an evidence of their impurity. The practicing physician should condemn and seek to avoid cheap druggists and cheap drugs as dangerous things to the success of his practice.

This crime of adulterating medicine and the dispensing of cheap, inferior and inefficient medicine has lost many patients their lives, and physicians their reputations.

To the honest, skilful manufacturer and druggist, both the profession and patients owe a great and lasting debt of gratitude. It is a genuine true pleasure and satisfaction to know that our prescriptions fall into the hands of such men.

There are pharmaceutical manufacturers whose productions never fail to come up to the correct standard, and druggists who never fail to compound their preparations correctly. It is only too true that there are others that cannot be depended upon. There should ever be existing a close, mutual relationship and confidence between the physician and druggist. It is of importance and advantage to both, and equally to the interests of both professions. As a means also of promoting negative medication, I desire to allude here to another criminal act on the part of dishonest druggists, the substitution of inferior and cheaper articles in filling prescriptions for those of purity and standard value. No one but a dishonest druggist could do this. And the man who would be guilty of committing this act would not hesitate to commit any other dishonest deed. He could not be trusted in anything. Yet we know that it is a not uncommon vice that our profession has to contend with. And it has been, and is being the means of defeating our success in our daily practice, and is an obstacle exceedingly difficult to deal with. The substitutor of drugs does not make a boast of dispensing cheap medicine, but sells for full price, and makes full profits, and until he renders himself liable to suspicion, makes his rascally business profitable at the expense of human life and professional reputation. When we order such elegant and pure drugs as Squibbs' chloroform, ether, ergot, we know what we are using. We expect certain positive effects and results. But when the dishonest druggist substitutes an inferior for a pure article, both the patient and physician are at his mercy. But, nevertheless, he goes on reaping enormous profits from his nefarious practice.

The great majority of druggists are honorable, high-minded men, competent in their profession, who would scorn to commit a dishonest act. But it is only too true that there is another class who are not above the grade of disreputable tricksters in the commonest and lowest trades of life. In this way the druggist who is guilty of substituting becomes an efficient agent for the promotion of negative medication.

In the past fifteen or twenty years there has sprung up all over the country, from hundreds of manufacturers, vaunted remedies under the title of "uterine tonics," for the cure of organic uterine disease. Under different appellations these preparations are sold and swallowed by the hundreds of gallons by females who are, or imagine themselves suffering from uterine disease. And these preparations are encouraged and prescribed by practicing physicians. I believe this to be one of the patent examples of negative medication.

I do not believe that there is on record a single instance of the cure of organic uterine disease by these remedies. Ergot has power to control uterine hæmorrhage and induce uterine contraction. Beyond these its therapeutic powers does not extend. Yet year after year the physician continues to lavishly prescribe these proprietary preparations when he must know that his results are negative. A remedy of this kind only has to be put upon the market and vaunted as a specific to meet with ready encouragement. The eagerness with which these remedies are caught up and used indicates the great difficulty of treating this class of affections and the disposition of our profession to catch at new and unknown remedies.

There is another subject of importance which is well calculated to defeat the positive action of our remedies, and I have no doubt has often been the means of obstructing our successful practice. I allude here to the common custom by druggists of the present time to facilitate business, of preparing decoctions and infusions of vegetable remedies from extracts often stale, or worthless. Many of our most important and efficient remedies are administered in this form. For instance the infusions of digitalis and ergot are remedies applicable to the treatment of some of the most dangerous forms of disease. Yet how common has it been in my own experience for an infusion or decoction of these drugs to be prepared from a worthless extract that fails to exert any positive action whatever. This is a question of such vital importance, the profession cannot afford to ignore it. I have on numerous occasions prescribed an infusion of digitalis in organic heart affection or pneumonitis and obtained not the least positive effect, and on inquiry found that the druggist occupied just ten minutes in making the preparation, when it should require one and a half hours to prepare an infusion or decoction from the leaf of the plant.

I then ordered an infusion from another druggist to be prepared in the proper manner, and found it all that could be desired. In the case of a female patient, long the subject of cardiac valvular disease, when extensive dropsical symptoms had supervened, I prescribed the infusion, or rather decoction of digitalis. The patient stated that digitalis would not benefit her in any form as she had taken it previously both in tincture and decoction without benefit. I then called on a skilled and reliable druggist and directed him to prepare for her a decoction from the digitalis leaf and consume an hour and a half in the preparation. The effects of this preparation after being administered twenty-four hours were of a most positive character, both on the heart and kidneys, and were such as to astonish my patient. That was twelve months ago, and there has been no return of dropsical symptoms since. The history of this case affords a very satisfactory example of the negative and positive action from the same remedy prepared in a different manner.

Thus, by different methods of preparing the same remedy we may obtain the most opposite results. The patient alluded to above, I discovered on investigation had formerly used tinctures and infusions prepared from fluid extracts only, which the druggist had made hastily in five or ten minutes, and was ignorant of the fact that he had furnished a worthless preparation and was impressed with the belief that he had prepared an elegant article with neatness and dispatch.

Probably at the present time the vegetable extracts enter more largely into the formation of our prescriptions than any single pharmaceutical preparation. And it is equally probable that they of all others are less reliable and more subject to adulteration and are made with less care and scientific thoroughness. It is also very certain that a very large proportion of these are utterly worthless and inert, and in their application we are using remedies that exert no influence one way or the other on the progress of disease. How this great and serious difficulty is to be corrected is a question in which all are interested. I am impressed with the conviction that it is not very difficult to do this and it can only be accomplished by the members of our profession giving their patronage to druggists and manufacturers of known character and established reputation.

There are firms having celebrated establishments for the manufacture of drugs of long standing and whose unvarying reputation for honesty and capability have established universal confidence and whose character is dearer to them than gold. These names, which it would be invidious to mention, we can trust, for they never deceive us.

For some years the fluid extracts as ordinarily prepared I have found to give so little satisfaction I now almost invariably prescribe a decoction or infusion prepared alone from the vegetable remedy in its native state, and I rarely fail to obtain positive effects. I often obtain absolutely negative results from the fluid extracts of ergot, uva ursi, digitalis and other vegetable remedies and get as certainly positive effects from the decoctions of remedies prepared from the article in its native state.

It is said that Lawson Tait found the extract of ergot so very unreliable that he now prepares a decoction from the grain at the time when needed for immediate use.

In a practice extending over many years I have seen so much of the evil effects of what I have here termed *negative medication*, or in other words, the absolutely negative results in the use of medicine arising from the various causes mentioned, I have come to regard it as necessary in any case undergoing treatment when the progress is either stationary or retrograding to consider the simple question whether the action of our remedies is positive or negative, certain or uncertain. Or on the other hand, whether the defect lies in our diagnosis, the inappropriateness of our therapeusis, or in quality, or method of compounding our remedies. Hence, in all cases where serious difficulties arise and the progress of the case is unfavorable, I have come to consider the questions of the character of the compounding druggist; the quality of the medicine prescribed, its solubility or insolubility and the possibility of adulteration or substitution.

Dr. Didama, of New York, said: I think we will all agree with the essayist that many pills do not give us satisfaction. He did not refer to the tablets which we have in soluble form. Most of these are readily soluble. Sugar coated and gelatine coated morphine pills will rarely dissolve. The administration of medicine in capsules is used a great deal; and some of us in the east are in the habit of administering medicines in wafers which are swallowed very easily by persons who cannot swallow a pill. We cannot control the druggist and we cannot always send our patients to the one of our choice, as patients have also their preferences. They take them often to the cheap pharmacist. The speaker favored the dispensing of drugs by the physician.

Dr. Wilson, of Kansas City, remarked that for twelve years he had been a druggist and during that time he had learned something. Since becoming a physician he had dispensed his own drugs, except for a short time. Since doing so he had largely increased his business. The pills of one of the large advertising firms in the United States will invariably pass through the entire alimentary canal without dissolving. The value of our work in the future, in dollars and cents, will lie in our dispensing our own remedies.

Dr. Herrick, of Cleveland, heartily agreed with the remarks that had been made. We are all witnesses, he said, of what Dr. Brown had said. He believed that the dispensing of our own drugs is in the way of progress. This is the custom in England and Europe. It can be done with little expense and trouble. It will greatly improve the quality and the taste of our medicines as well.

The next paper read was entitled

A CASE OF AMŒBIC DYSENTERY.

BY E. P. GERRY, M.D.,

OF JAMAICA PLAINS, MASS.

In calling attention to the amœba dysentariæ, the nomenclature of Councilman and Lafleur has been followed, instead of Lösch, who in 1873 first described the organism under the name of amœba coli. As Councilman and Lafleur say in their admirable work on amœbic dysentery, the name amœba coli is not distinctive, for it is very probable that there may be a number of species of amœbæ which, under certain conditions, infest the colon.

They quote Cunningham, of India, as having found them not only in human fæces, in health and disease, but also in the fæces of some of the domestic animals It therefore seems proper that the more distinctive name is the one by which the organism should be known. Lambl in 1859 discovered certain organisms belonging among the protozoa in the intestinal contents. They produced a dysentery which baffled most observers as to its significance, even in countries where climatic conditions oftenest produced it.

Although ably studied and described by Kartulis in Egypt, as early as 1885, it did not attract that attention which such work deserves. Everywhere the mind of the investigator has been largely filled with such important subjects as bacteriology, etc.

In this country the name of tropical abscess, or dysentery, suggested at such a distance from that latitude, that the likelihood of its occurring among us of the temperate zone was hardly thought of, until Osler, in 1890, first found and described it, and made it evident that it might be brought to, or even originate in a northern country. Since then cases have been found of which the one to be related is a type, which occur unexpectedly, probably from the same but restricted causes which produced the condition in warmer climates.

That they have been unrecognized is undoubtedly true; that this disease occurred in the United States before it was recognized is also true, for Councilman and Lafleur, after a very careful study of the specimens of dysentery in the Army Medical Museum, found undoubted traces of amœbic dysentery. The specimens came mostly from soldiers who died of dysentery during the late war, remaining undescribed until Osler's discovery in 1890 led his colleagues to give special study to all quarters where the disease was liable to be found. In view of these facts it i fair to suppose that the profession in America knew very little, if anything, of this peculiar form of dysentery until Councilman and Lafleur presented a complete history of it.

That such a disease with such a cause existed was a revelation to the reader. The object of the paper is to call special attention to it, so that some professional brother may be *able to correctly diagnose* such a case and properly treat it. That the profession at large is as well informed as it should be on this topic can be doubted. There is no question but that the members of such a National body as the American Medical Association should be urged to study the subject thoroughly, for the authorities say that it is found in most parts of the United States.

More than in most diseases does correct diagnosis make successful treatment possible.

That amœbic dysentery is a form of dysentery which etiologically, clinically and anatomically, should be regarded as a distinct disease, it seems as if no one reading the experiments of Kartulis can doubt. Some will ask, Has he followed Koch's canons; first, by proving that the amœbæ existed in enough cases to make it reasonably certain that they will not be eliminated as the cause of the disease; second, has he been able to cultivate them outside of the body (under artificial conditions); third, when cultivated, has he been able to produce characteristic symptoms when reintroduced into the bodies of animals. Kartulis says he has.

He injected into the rectums of cats the cultures obtained, and found as a result the colon swollen and lax, with occasional small erosions, but no regular ulcers. Hlava, of Prague, supports him in his position, for he injected the stools containing amœbæ into the rectums of dogs and cats, with positive results in two dogs out of seventeen and four cats out of six. Baumgarten, however, although not contradicting Kartulis' positive statements, thinks it more probable that the pyogenic microörganisms play an important part along with the amœbæ in the production of tropical abscess.

That it is difficult to tell absolutely just what they will do, and where they will be found is likewise difficult, for they are reported as having been found in the bladder and vagina of a tuberculous case. That they produce abscess of the liver has long been known, and that they work their way into the lung is now recognized. That the disease has so long been unrecognized and unstudied in this country, and that the principal literature on this subject has come until recently from Kartulis in Egypt, and perhaps Cunningham in India, has been due to the fact that cli*matic conditions in those countries* produced more of it than among us. It is only, as it were, accidentally, that Osler had a case come to him.

The case to be reported is as follows:

Miss F., aged 25, family history excellent, unusually strong and well until August, 1890. She had, however, lost color for about a year previously, supposed to be due to taking care of her mother, who died with bronchial trouble.

She was somewhat debilitated at that time, but regained her flesh and strength some months later, but not her color. In August, 1890, she noticed a single solid, whitish discharge from rectum, like a white clot. Her bowels then became constipated, and after a month, occasional small discharges of *bloody mucus* were *noticed*, containing numerous white specks and streaks. These persisted despite the various remedies that were used. *She had three or four* discharges daily, mixed with more or less semi-solid or liquid fæces of a brown color. At one time after treatment began, in September, 1890, she was very constipated, not having an operation for eleven days. After that time, she *noticed that the* bowels did not seem to act naturally, whether constipated or loose. At intervals the quantity and number of blood-stained stools were lessened under treatment, although they never became quite normal. They were *perceptibly* fewer during the early summer months of 1891, especially so while at the sea-shore.

The last week of September, for a week or ten days the stools became more bloody, and she had as many as a dozen or fifteen daily for a few days. During September and October the stools became more offensive than usual, though they were noticeably so during her illness. This attack came on while she was in extra strength and weight, the result of the sea-shore vacation. *In fact, she only became* emaciated when the severity of the symptoms increased. No important loss of strength and weight had been noticed during the year she had been passing blood-stained fæces. *The evacuations had been painless*, and unaffected by food or drink. In fact, *pain had not been a symptom*, either in the epigastrium or other part of abdomen. There had been neither nausea, tenesmus or jaundice. During October tenderness was noticed in right iliac fossa, but there was no dis*tension until* October 23. On that day the bowels began to be somewhat distended and tympanitic, and the tenderness extended upward, nearer the liver, becoming more severe and producing a feeling as of a bunch under fingers.

This was the first time that there had been any swelling. The temperature was 101°, pulse 120. There was loss of appetite, drowsiness and some slight sweating. Fever was a new feature, but the pulse had run from 100 to 120 since September. Micturition became more frequent. Examination showed no uterine trouble. As a rule she slept well during her illness.

After she was confined to her bed, she was in the habit of lying on her back with knees drawn up a considerable part of the time, as a lateral position produced an inclination to evacuate the bowels. Diagnosis of dysentery from ulceration was early made, and injections of liquor bismuth, etc., were given, and bismuth by mouth, during the year she was under treatment before the amœbæ were discovered.

The marked intermissions in symptoms raised the hope that treatment had been successful. The violent attack in September again called attention to the dysentery, and diet and treatment were directed towards supplying the patient with food that would not irritate the bowels and with medicine that would stop the bloody stools. Peptonized milk was given as the only food for a week or two, of which she took about two quarts daily, then Valentine's meat-juice and egg-nogg were added. Opium and camphor pills were given after a short course of teaspoonful doses of castor oil. The oil appeared to relieve, but was abandoned because it was feared that instead of relieving the dysentery, it might be continuing it. As the bloody discharge continued, gallic acid was given, with the effect of diminishing the blood in the discharges. The rectal treatment consisted of injections of sulphate of zinc.

The febrile attack with tympanites, etc., October 23, with the extension of tenderness and the appearance of a hard place under the liver, led to a consultation with Dr. R. H. Fitz, of the Harvard Medical School, who made a diagnosis of "chronic, ulcerative colitis, acute paracolitis and probably amœbæ dysenteriæ," which he verified microscopically. *In his report of the case* he says: "The abdomen was slightly and symmetrically distended, tympanitic everywhere, except over a space as large as *the palm of the hand*, at the right of the navel, between the costal cartilages and the anterior superior iliac spine, extending *nearly to the median line*. The dull region was tense and tender, resistance gradually lessening toward the edge; there was neither elasticity nor a sense of fluctuation. There was slight tenderness in the hypogastrium just above the symphysis. The liver dulness was slightly increased; there was no tenderness in the hepatic region; the splenic dulness was somewhat increased.

"The rectal examination was negative. Two stools, seen at this time, were homogeneous, soft, pap-like in consistency; they were of a brown color, mixed with red from the presence of blood, and in one were clumps of reddish mucus, translucent, *like sago grains*.

"The fæces were examined microscopically, at intervals, during a period of several *days, and amœbæ* were always found. They appeared as round or slightly oval bodies, varying somewhat in size, but in general, with a diameter six or seven times that of a leucocyte. The periphery often appeared like a homogeneous, hyaline membrane, while the body of the amœbæ was composed of coarse, gray granules.

Within the body a nucleus was often to be seen, also vacuoles, and occasionally, one or more red blood corpuscles.

"The fæces were brought from a distance of several miles during cold weather, and the amœbæ were always motionless, even on the hot stage. In only one instance were pseudopods present, but they remained quiescent during a period of several minutes. The diagnosis of a paracolitis in this case was suggested by the acute, febrile attack connected with the limitation of the sudden and sensitive induration to the course of the ascending colon, the absence of a sharply defined edge, and the failure to appreciate the fluctuation or elasticity which usually accompany an encysted fluid near the abdominal wall."

Just here special attention is called to the problem presented to Dr. Fitz. The case was classified as one of dysentery, although there had been neither painful stools nor bowels during most of the sickness. An ulcerative cæcitis or colitis of malignant or tubercular character was suggested by both positive and negative symptoms. Suddenly a tense, tender, non-elastic, non-fluctuating bunch was found under the liver, accompanied by febrile symptoms. An abscess appeared imminent. What did it mean and what must be done? Dr. Maurice H. Richardson, Massachusetts General Hospital, was summoned to determine if anything surgical should be done. After two visits he was not positive. and asked that Dr. Fitz see the patient. In view of what the case proved to be, one can imagine what a blunder surgical interference would have been, and the brilliancy of the diagnosis which perhaps prevented even an exploratory incision.

High rectal enemata of dilute solutions of quinine (1 to 5,000) were recommended. These injections were given cold, morning and evening during November and December; a soft rubber rectal tube was used, which was inserted as far as possible, patient lying on her right side, hips elevated, gentle friction being employed along the colon. At first no change or improvement was noted, but after a time it was evident that the dysentery was better. The passages were less frequent, the necrosed tissue was less abundant and the amœbæ began to disappear from the stools, frequent microscopical examinations being made. Notwithstanding these improvements the marked anæmia persisted. Œdema appeared in one ankle, then after a time in the other.

Nausea and occasional vomiting of food and large quantities of mucus, with loss of appetite, probably from irritation in the colon, showed that the stomach was feeling the strain. Progressive loss of strength was apparent, and the outlook was discouraging. This was made more so by the exacerbations, which would prostrate her just when she seemed to be improving. It was feared this was due not only to the loss of blood she had sustained but, as was suggested, to the fact that the amœbæ were destroying the red blood corpuscles. Still she did gain, despite the weakness which was always present. She began to sit up, and the day before Christmas wrote a letter. Christmas day and the day following she did not feel very well, although there was nothing apparent more than there had been a number of times before. December 27 pneumonia set in, and she died early in the morning of December 28, during the week when la grippe invaded Boston, and to which she fell an easy victim. During the last month of her life, her abdomen continued tympanitic, but the bunch under her liver became smaller and tenderness almost disappeared.

The autopsy, as reported by Dr. Fitz, showed that for some 7 inches below the cæcum, the inner surface of the intestine was trabeculated and undermined, a lace-like covering and granular projections being present. The rest of the lining of the colon showed an irregular, lobulated thickening The muscular coat was thickened and the canal diminished. The entire inner surface was of a dirty greenish-gray color. About the middle of the ascending colon, the mesocolon showed a localized dilatation and injection of the vessels. On microscopical examination of secretions from the ulcerated intestine no amœbæ were found.

Authorities state that the amœbæ probably reach the large intestine in the food and drink; that they exert no action on stomach or small intestines, but only when they reach the large intestines, where they find favorable conditions, namely: an alkaline material. If water contaminated by organic material is a source of this disease, how important a subject the purity of our water supply is. The clinical history of such a case is characterized by a variable, perhaps uncertain opening, marked intermissions and exacerbations of bloody stools, having in them what one learns to recognize as necrotic tissue of a grayish-brown color; Councilman reports one measuring 11 centimeters. Tenesmus is generally not a prominent feature. Anæmia is usually well marked.

The pronounced tendency to chronicity adds discouragements to the case. The diagnosis being made positive by the presence of the amœbæ in the stools, certain physical characters different from those seen in the stools of other forms of dysentery present themselves. Councilman says they are rather more numerous in the small gelatinous masses found in the fæces. Their number is generally proportionate to the severity of the lesions. The report referred to cites a fatal case, however, in which no amœbæ were found until after death, although there were extensive sloughs from cæcum to anus. Prognosis depends upon the quickness with which a correct diagnosis is made and the thoroughness of the treatment. Diagnosis having been established, the organisms must be destroyed. An important clinical fact is the undoubted curative value of simple cold water injections containing either quinine or boric acid. Eichberg, of Cincinnati, suggests that as warmth favors the multiplication of organisms of a low order, cold either destroys their vitality entirely, or suspends it sufficiently to enable the bowels to throw off the organisms.

The paper offered is principally a clinical picture of what was to the reader a very interesting and little known form of disease. It is presented by a general practitioner to general practitioners.

It is eminently proper to acknowledge indebtedness to the thorough work done at the Johns Hopkins Hospital, for much valuable information and literature regarding the subject.

Dr. Herrick remarked that it would be interesting to know how the amœba gets into the alimentary canal. Other elements are involved. Is it not true that the circulation of the abdominal organs is largely controlled by the liver. This organ, he thought, had a great deal to do with the disease. He attributed it to the use of too much amylaceous matter.

Dr. Didama thought the remarks of the last speaker not very pertinent to the subject under consideration, and requested that in the future the remarks be confined to the subject under consideration by the essayist.

Dr. Musser, of Philadelphia, thought we should be thankful to the essayist for his paper, because in it we have without doubt a positive addition to our knowledge regarding the pathology and physiology of occurrences in the alimentary tract. He had been much interested by the narration by the essayist of a case of this kind occurring in the North. This form of dysentery was formerly supposed to be of tropical origin only. But since the first observation of Dr. Councilman, who read a paper before the American Association of Physicians, reporting a case which occurred in Canada, the possibility of its occurrence in northern regions must be conceded. It is doubtless more common than is supposed. The speaker then reported a case which favored the view that the disease is of tropical origin, or at least more likely to occur in persons who have resided in the tropics. The case was one of a woman past middle life who was born in Cuba, but a resident of this country for fifteen years. She had never had any bowel trouble except in early life. She had an attack of acute dysentery, as we are accustomed to recognize it in this climate, all the manifestations differing in symptomatology in a large measure from those of ordinary dysentery. There was fever, pain and the characteristic dysenteric stools. With Dr. Guiteras, the stools were examined by the speaker. They were able to find in the masses to which attention has been called by Osler and Councilman, the living organisms, moving with all the characteristics of a living amœba. The clinical history of the case was otherwise that of an ordinary case of dysentery.

He did not resort in the treatment to the injection of quinine, which is probably the best remedy, particularly in the chronic form of the disease. He had referred to the case, he said, because in the first place it was another case occurring in the North, and because it presented the ordinary symptoms of dysentery, and finally because [illegible] lieved by saline cathartics and other [illegible] resorted to.

The next paper was entitled:

RETAINED FECES.

BY W. S. CHRISTOPHER, M.D.,

PROFESSOR OF DISEASES OF CHILDREN, CHICAGO POLICLINIC.

The French, perhaps, more than any other people, have studied the effects of retained feces. Stercoræmia is a common word in their writings. Bouchardat particularly has investigated this subject, and has studied its relations to impairment of hepatic functions. It is not, however, my purpose to review the literature, but to call attention briefly to a few features of the subject, with a view to opening a discussion.

From experience gained by the frequent use of lavage of the bowels, I am almost ready to believe that a greater or less retention of old feces is a normal condition. At least I have frequently washed out from bowels that were apparently normal, old scybalous masses, which could hardly be charged with either local or remote effects.

Feces stranded in the cæcum may do no harm, but they are a constant menace. Sooner or later they may set up typhlitis, a disease which I believe exists as an entity notwithstanding recent pathological reports and the somewhat strongly expressed views of some modern abdominal surgeons. Typhlitis once inaugurated, a long series of disasters may follow, to which the somewhat indefinite name, right iliac disease, might with propriety be given. I can heartily agree with Jules Simon that the great danger of typhlitis is appendicitis, but cannot agree with the view which is so commonly held at present, that the initial factor in right iliac disease is always appendicitis. The mechanism by which appendicitis and the subsequent peritonitis are produced is not clear, but some recent observations by Adenot, of Lyons, would indicate that the bacterium coli commune is to blame. This ordinarily innocent inhabitant of the bowel, seems to acquire virulence in the presence of catarrhal conditions of the bowel, and then becomes capable of giving rise to appendicular and peritonitic disease, and even the so-called perityphlitic abscess.

Impaction of feces so extensive as to produce actual obstruction of the bowel is certainly uncommon, but localized impactions giving rise to localized peritonitis, and even peri-colonic abscess, are not rare. I have recently had a patient with serious stomach disorder secondary to an obstructive heart lesion, who developed in the region of the spleen, a most intense localized peritonitis. Lavage of the bowel was rewarded with the removal of a large mass of scybalous feces, and great relief to the localized tenderness. Some relief was also afforded to the severe vomiting present.

But the local systoms resulting from retained feces are not the most interesting or the most important.

Retained feces usually putrefy and give constantly to the blood stream a supply of poisons of the most varied type. When this supply is small, the liver changes the poisons into innocuous substances and no harm results. But when the supply is large, or the liver incompetent to perform its function in this direction, these noxious substances gain entrance to the general circulation and produce the most varied symptoms. We have then the stercoræmia of the French.

Headache is a common symptom resulting from this condition, and the old fashioned and much maligned biliousness is another. Fever often occurs, and to this fact is due the wide spread belief among the laity that castor oil is good for fever. Skin eruptions are frequent, and are only permanently cured when the source of the poison producing them, is cut off. Sir Andrew Clark has expressed his belief that the best remedy for anæmia is a laxative. This bold statement, often true, serves to call attention to the undoubted fact that stercoræmia is a frequent cause of anæmia. A clinical picture which I have often seen, is the following: First, constipation, then putrefaction of the retained feces, then stercoræmia, then anæmia, then as a result of the impoverished blood, incomplete nourishment of the various organs of the body, then defective secretion, particularly defective gastric secretion, then dyspepsia, then improper digestion and assimilation of food, then increased anæmia. Thus a vicious circle is formed, which tends constantly to increase the pathological conditions present. Certainly iron can be of but little service under such circumstances. To effect a cure the retained feces must be removed, before attention need be directed toward the other conditions.

The following case, when first seen was suspected by my assistant to be one of tubercular meningitis:

Mary S., age 7 months, had scarlatina four weeks ago, and had diarrhœa while the rash was on her. Now she does not take the breast, and is feverish at times. Is sleepless, and has been given soothing syrup. Rectal temperature 103. Pupils react very slightly and are even. Abdomen somewhat retracted, bowels constipated. Tâche rouge appears and disappears slowly. There are some rose colored spots on the abdomen which do not react like typhoid spots. Urine dark and of bad odor. There is a whitish film on the alveolar process. Expression is stupid, has a whining cry, and keeps her finger in her mouth. Believing that the case was only one of constipation, I gave the baby three one-grain doses of calomel, with the result of removing from the bowel a large mass of putrid feces. This was accompanied with a great amelioration of the symptoms, and a few days more attention to the bowels in the same direction, completely cured the child.

It would be tiresome to attempt to enumerate all the symptoms which can be produced by retained feces. It is probable however, that any symptom which can have its origin in an action of the central nervous system can be initiated by the poisons produced by retained feces.

I shall content myself with relating two cases which are of more than ordinary interest.

Mrs. L., age 60, is a very obese woman, weighing ordinarily 210 pounds. When I first saw her last October, she had been confined to her bed for two months. Partly owing to her great weight, and partly apparently from some degree of paresis she was quite unable to turn herself in bed. During the preceding two months she had had occasional irregular febrile periods. At the time I first saw her she was vomiting persistently, being utterly unable to retain the milk and lime water which was being fed to her. In addition there was complete incontinence of urine and feces, which passed from her without her knowledge. Her pulse was weak and her general condition bad. The outlook was very gloomy. The diagnosis lay between structural disease of the spinal cord and constipation. For the latter diagnosis, there was no positive evidence whatever. Her obesity rendered it impossible to determine the condition of the colon. The diagnosis of possible constipation was made, however, because all the symptoms present could be explained by such a condition and any other diagnosis meant abandonment of the patient to her fate. She was given copious enemas of water, which brought away large quantities of hard, lumpy, feces, covered with mucus and some pus, and having a very putrid odor. These lumps continued to come away with the enemas for two weeks. Improvement quickly set in and in about a month she was well. Last week I saw the old lady, perfectly well, and unusually active for one of her age and weight.

The next case is one which occurred in the practice of Dr. Harold Moyer of Chicago. It is the most remarkable instance of the evil results which can follow from retention of feces, which has ever come to my notice. I quote in full Dr. Moyer's report of the case, as published in *The Alienist and Neurologist* for January, 1890.

"July 17, 1887, I was summoned to an adjoining city to see Mrs. G., in consultation. The attending physician furnished me with the following account: Father of patient living and well; mother died of cancer of the uterus. No trace of insanity in the family, or neurotic heredity of any kind. Her health previous to the present difficulty had been fair, an occasional cough, with inflammation of the pharynx, being her only illness. Menstruation appeared at fourteen, and was always normally performed. Married at twenty-three, and at twenty-five, had a premature labor, this accident not being followed by any disturbance of the general health. Present illness began about eight months ago, and was marked by an increasing general debility, loss of appetite, decrease in weight, and obstinate constipation. The symptoms did not point to a change in any particular organ. Six months later, had sudden attacks of fainting. occurring at irregular intervals. These attacks would begin with pain in the left hypochondrium and a sense of suffocation. Within the last six months, tenderness on pressure has appeared in this region, and the attacks have become more frequent, and are accompanied by vomiting. During this time she had no febrile reaction, but was nervous, excitable and affected with morbid fears. This was substantially her condition until three months before she came under my observation, when she began to show positive signs of insanity, was restless, sleepless and incoherent, with confusional hallucinations and non-systematic delusions of a depressed and melancholy character.

Examination of the patient shows the muscles and fatty tissues wasted to the last degree. The flexor tendons of the thighs are contracted, so that the legs cannot be extended. The skin is of a dirty brown color, and covered with branny scales. Eyeballs prominent, pupils react normally. Ophthalmoscopic appearance of fundus normal. The heart, lungs, kidneys and sexual organs were carefully investigated, and nothing abnormal noted. A line of superficial dulness could be made out, extending transversely across the abdomen, on a level with the umbilicus, and a lobulated mass could be felt in the left inguinal region, but it could not be distinctly outlined. The temperature was normal. Pulse weak and variable, from 120 to 140 per minute. The mental symptoms were substantially those which were described as existing for the past three months.

A diagnosis of an exhaustional confusional form of insanity, proceeding from a dilated and over-filled colon, was made. Large rectal injections were ordered, containing in each pint of water two ounces of listerine and one drachm of common salt. Tonics were also ordered with cod-liver oil innunction, massage and general faradization.

The subsequent history was furnished by the attending physician.

July 19. Condition unchanged, absolutely refused food. Insisted that her brother had been recently killed.

July 20. First injection given, consisting of about two pints. The tube was passed well beyond the sigmoid flexure. In about an hour the injection came away and with it a considerable amount of fecal matter. Upon withdrawing the tube, its distal end was found to be coated with dark, waxy, adhesive fecal matter, entirely unlike that which came away. After the injection the patient passed into a quiet sleep, from which she was awakened after about two hours, and called for food for the first time in many weeks.

July 21. Marked improvement; pulse 100. No fecal masses came away with to-day's injection, but the tube is still coated as at first. showing that a mass is still retained. Mind perfectly clear and tranquil.

July 30. Continued improvement. Since beginning the treatment ten rectal injections have been given. Occasionally a dark, hardened fecal mass comes away.

August 14. Able to be out of bed, but walks with great difficulty, owing to the muscular wasting. Mind perfectly clear, but retains only an indistinct recollection of the time of her illness. For the past two weeks her bowels have acted without cathartics, and her appetite is excellent.

Nov. 20. No longer suffers from constipation, and her health is better than it was before her illness."

It is not an easy matter to empty the colon of feces which have been long retained. Active cathartics will not suffice. Indeed their prolonged use, or rather abuse, is a most potent factor in the causation of the condition. Salines in moderate quantities will sometimes succeed in washing out the retained masses, but after the abuse of purgatives, a sedative is often the most effectual in clearing the bowels. A most useful one under such circumstances is a pill containing iron and belladonna. I have found the bowels to act after a few days' rest, when croton oil had failed to produce an evacuation. But the most satisfactory plan for relieving the colon of retained feces, is the use of lavage. Copious injections of warm water will dislodge masses of feces that cannot be removed in any other way. It should not be forgotten that several injections may have to be given before any old feces will be brought away, and that it often takes daily injections for several weeks to completely empty the bowel, and entirely remove all the old hardened, dark feces.

The following conclusions are submitted:

1. Long continued partial retention of feces is common.
2. Such retention is usually harmless.
3. Retained feces undergoing putrefaction may, at any time, acquire poisonous properties.
4. Retained feces may produce either local or constitutional symptoms.
5. The principal local conditions produced by retained feces are typhlitis, appendicitis, and peritonitis, either localized or general.
6. Retained feces, through the poisons produced in them, are capable of causing any constitutional symptoms which can be manifested through the agency of the central nervous system.
7. Among the toxic effects of such stercoræmia may be mentioned fever, convulsions, coma, insomnia, headache, neuralgia, vertigo, anæmia, diarrhœa, constipation, incontinence of urine and feces, insanity, etc.

Dr. N. S. Davis, Jr. of Chicago, remarked that there are in addition to the cases referred to by the essayist, other cases in which there is a moderate amount of retention of feces. There are cases in which there are regular movements of the bowel, but not thorough evacuation. The symptoms of more or less distressing character are promptly relieved by free evacuation. The symptoms are most frequently some pain in the back; sometimes a slight, but usually a considerable degree of anæmia. These cases are frequent. The daily movement is rather a spilling over of the bowels, than a movement. Only a comparatively small amount is evacuated, and not enough to relieve the retention which exists. These cases can be relieved by enemas.

Dr. Herrick spoke of the retention of feces as due to disorders of intestinal secretion.

Dr. Fuller, of Massachusetts, reported at some length the case of a woman whom he had relieved seven times of a fecal impaction, following childbirth, in whom the autopsy revealed several regions of intestine in which the walls were so thickened, as to narrow the calibre to so great an extent that the finger could not be made to pass through.

Dr. Newcomb, of New York, referred to two cases similar to those which had been described. One was that of a man brought into the hospital in a moribund condition. The autopsy revealed no lesion of serious nature except that the entire colon packed full of hardened feces. The speaker had also made some investigations in regard to the anæmia which is relieved by laxatives. He had been engaged in the investigation of the blood of his patients whom he was treating with the chalybeate pill. He concluded to test the efficacy of laxative treatment without the administration of iron. He found that up to a certain point the patients seemed to do just as well as they did under the Blaud's pills, but beyond that the iron was required. He had concluded therefore, that, as Alonzo Clarke has asserted, the most important factor in the production of anæmia is the imperfect action of the bowels.

Dr. Greenlee, of Kentucky, reported a case of impaction of feces in the sigmoid flexure.

Dr. J. M. Anders, of Philadelphia, agreed with the essayist that typhlitis is an entity, and as well in regard to the stercoræmia of the French. He believed also that the fever is sometimes attributable to this cause. In a certain class of cases, however, another explanation must be had. In many of these cases, no doubt, the retained fecal matter acts as a mechanical irritant to the coats of the intestine, setting up a catarrhal condition. This condition is frequently not followed by diarrhœa, but tends to increase the constipation. Owing to this condition we have absorption markedly interfered with. In many of these cases, indeed, I have no doubt that the final condition, fecal impaction, stands in the relation of cause rather than that of effect.

Dr. S. Solis-Cohen, of Philadelphia, said that the paper was of interest to him because he had seen several cases similar in character to those reported by Dr. Christopher. One remarkable case occurred occurred in connection with laryngeal ulceration. The early symptoms pointed somewhat to typhoid, but the later course of the case was such that this disease could not be diagnosticated. It was decided to be a case of stercoræmia and was promptly relieved. In another case he was summoned in great haste to a patient of a homœopath who was said to be dying of "pneumonia." Physical examination showed entire absence of pneumonia. There was rapid breathing, great depression, temperature 102° or 103°. Impaction of feces was discovered and treatment promptly dissipated the supposed threatening pneumonia.

In the clinic of Professor Bartholow, of Philadelphia, several women presented themselves who feared that they had committed the unpardonable sin. Professor Bartholow promptly diagnosticated the cases as those of obstinate constipation. Gross, the speaker said, has given us the term, "incontinence of retention," and so we might say, the diarrhœa of constipation. Among the other blunders of diagnosis which had come under his observation, the speaker mentioned that in which confusion had arisen between fecal impaction with its attendant pain and renal colic, in which irrigation of the bowel promptly dissipated the symptoms.

Dr. Christopher, in concluding the discussion, remarked that he also had seen confusion between fæcal impaction and renal colic. Not long ago a patient had presented himself who supposed that he was suffering from the passage of a gall-stone. Being always inclined to test the possibility of its being due to fæcal impaction, he ordered copious injections of hot water. The pain was much ameliorated by the enemata, but after a few days the patient again presented himself carrying with him a renal calculus which he had passed. Yet an important lesson was found in the fact that the hot water injections to so great an extent relieved the pain of the renal colic.

The speaker thought that if we would give up the treatment of diarrhœas with bismuth and opium, and treat it like our fathers did fifty years, by the administration of a copious dose of calomel, our results would be better. I am convinced, he said, that many of the diseases which go by the name of "itis" at their termination are due to auto-intoxication from retained fæces.

(To be continued.)

Scarlatina.—Lauder Brunton speaks favorably of arsenic, when the tongue remains red and irritable during convalescence. Carbonate of ammonium in frequent doses is greatly recommended.

Ringer recommends chlorine-water for sloughing throat; arsenic and nitric acid for persisting red tongue in convalescence; cold compresses to the throat throughout; ice to be sucked; gray powder for inflamed tonsils; packing throughout, especially on retrocession of rash; veratrum for convulsions.—*Times and Register.*

NOTES ON SOME INTERESTING CASES AT THE NEW YORK MOTHERS' HOME MATERNITY HOSPITAL.

BY T. J. McGILLICUDDY, M.D.,
SURGEON TO THE YORKVILLE DISPENSARY AND HOSPITAL FOR WOMEN AND CHILDREN, ETC.

In May, 1888, the New York Mothers' Home Maternity Hospital began its work in this city. It is located at 531 East 86th St., in a large double house containing thirty rooms. This building has been completely renovated and very particular attention was given to the plumbing, it being entirely renewed. The institution also includes within its grounds 525 E. 86th St., a three story frame house of ten large rooms. These buildings, however, are simply for temporary use, as the erection of a wing to the large new hospital has been started; the size of this wing is 65 by 140 feet, and it will be five stories high. The class of patients received are as a rule the poor and unfortunate, and no discrimination is made in regard to religion, color or nationality. Extreme cleanliness is the rule throughout the whole institution, an important part of which is the laundry, it being in constant requisition, and all the clothing is boiled in an antiseptic solution. The pregnant, parturient and puerpural women are kept separate. There is a special room for delivery on the same floor with the lying-in wards. On another floor a special separate room for any case of fever that might possibly develop, but it has never been necessary to use it for that purpose. There is also one room set apart for any serious operative case, and there are also rooms for private patients. The food supplied is wholesome and plentiful, and suitable to the condition of the inmates.

Every patient on entering is given a general bath and has her clothing changed. Her urine is examined, her condition noted, and she is prescribed for if any remedy is indicated. In the delivery room during attendance on the parturient woman all the usual antiseptic precautions are taken, the hands being frequently dipped in a warm solution of creolin. The discharges are received into a pad of muslin about two and a half feet square and rendered thoroughly aseptic. After labor in cases where it is indicated the vagina is douched with simple warm water that has been boiled, or warm water with creolin added. This solution is also used for small lacerations or abrasions of the vagina.

Lacerations of the perineum if at all extensive are sewn immediately. The binder used is of aseptic muslin doubled, about three feet in length and fourteen inches wide, rather thick and soft, thus coaptating smoothly to the patient's shape, and a similarly shaped piece is folded and placed against the vulvæ. This pad being large and thick absorbs the lochial discharge and is changed frequently. Ergot is very seldom used and then only when good contractions of the uterus cannot otherwise be obtained. The stronger patients are permitted to sit up for a short time on the sixth day but they remain most of the time in bed for ten days. Every patient is expected to nurse her own child unless there is some contra-indication. Several of those admitted were either tuberculous or syphilitic, and had been refused admittance to other institutions. Others were addicted to spiritus frumenti or had suffered from insufficient food and hard work.

The infants have a large bath room, each one having a separate bath tub, and a large drawer containing its own towels, soap, powder, etc. In cases of ophthalmia neonatorem, the treatment consists of applications of a two per cent. solution of nitrate of silver, frequent cleansing, and if the inflammation is very acute, iced applications are made.

Since the opening of the hospital in the city to May 1, 1892, there have been five hundred patients delivered with but two deaths from puerperal disease, and when we consider their condition on entering, most of them being homeless or from tenement districts, having been without fresh air or wholesome food and often in a wretched physical state, this record is indeed very good.

One patient was taken ill in February, 1890, with the prevailing catarrhal influenza or la grippe. She was far advanced in phthisis, and died from pneumonia nearly a month after her confinement. Three of the patients suffered with acute croupous pneumonia shortly before and during labor, but it in no way interfered with the delivery or the convalescence. Having been the only visiting surgeon for most of the time since the hospital was opened and having seen all these cases, I think that a few notes on some of them may be of interest.

Case 1.—Funis Presentation.—This patient was a tall, unhealthy looking primipara, æt 24. The head presented with the cord which had several inches prolapsed, and was found to be pulsating irregularly. A catheter and tape was first employed for its reposition, but the tape constricted the cord to such a degree that the method was condemned as dangerous, and the patient was placed in the knee and chest position as advocated by Dr. Thomas, and the cord replaced by the fingers. The forceps was then resorted to but the child was dead when delivered. There was also a second case of funis presentation occurring in a still birth at seven months.

Case 2.—Contracted Pelvis.—Æt 19, primipara, patient is very lame, there being a difference of two and three quarters inches between the length of the lower limbs. The left leg is well developed, while the right is stiff and small, the result of an unreduced dislocation of the head of the femur when she was a child. Pelvis at the brim D shaped, the abridgement being on the right side and the narrowness in the transverse diameter. The child's head in descending passed to the left curving around the obstruction. The contractions of the uterus were exceedingly strong, and the head would strike with each pain so forcibly against the obstruction that I believed that the safety of the child demanded immediate delivery, and applying my axis traction forceps it was easily performed. The child was apparently all right but after twenty-four hours a large hæmatoma was found under the scalp on the right side from rupture of the temporal artery caused by the pounding of the head against the deformed brim of the pelvis. The child died in thirty-six hours.

Case 3.—Contracted Pelvis.—Æt 28. On the entrance of this patient she brought a note from a physician in this city in which he said craniotomy would probably be necessary for the delivery. As far as I could learn from the patient and her friends she had been in labor for six days, most of the time with a midwife, three physicians had been consulted and two of them after an examination had come to the conclusion that craniotomy would have to be resorted to. The patient was in fair condition and on making an examination, I found some contraction of the conjugata vera.

The head wedged in a transverse position, I applied my forceps with one blade over the face and the other over the occiput, drew it down into the cavity of the pelvis and then rotating the occiput forward, reapplied the forceps to the sides of the child's head, and the delivery was easily accomplished. The sides of the parietal bone where it came in contact with the sacrum was marked by an abrasion which afterward sloughed. Both mother and child did well.

Case 4.—Congenital Dislocation at the Knee.—Æt 24. Primipara. In slow and dry labor for twenty-eight hours. Breech presentation with limbs reflected on the body. When the cervix was thoroughly dilated, the labor did not advance as it should, and after each pain the breech would disappear into the uterus as if some obstruction was present and forced it back. The nurse made the remark "that something is keeping the child back." The accompanying photograph taken the next day shows the dislocation and position of the leg which during and after the delivery was approximated tightly to the front of the body. The dislocation reduced itself naturally and the knee became all right.

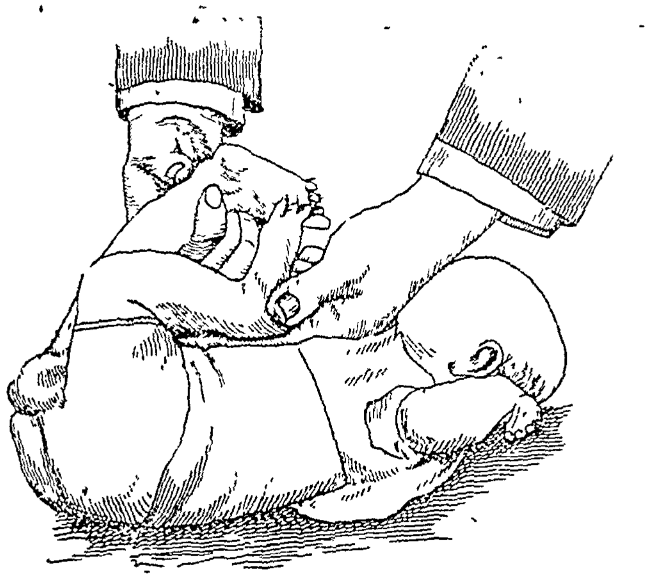

FIG. 1.

Puerperal nephritis is of so frequent occurrence and of so much importance that it is hoped that the following will be of some interest to the reader: Thirteen cases of puerperal nephritis were noted, and there were seven cases of puerperal eclampsia, one of them being fatal. The treatment of puerperal eclampsia where prophylaxis of the disease has not been attempted, should consist of *washing out* and purifying the blood, digestive and genito-urinary tracts, removing the renal congestion, quieting the nervous system and renewing the supply of normal healthy blood by the ingestion of a proper diet both liquid and solid, and mental as well as physical rest along with plenty of fresh air.

Case 5.—Puerperal Eclampsia. Twins. Very Pendulous Abdomen.—Æt. 29, primipara; very thin and delicate, weighing about 100 pounds, has an extremely pendulous abdomen. Labor begun at 9 A.M.; at 3 P.M. the first stage was completed; at 7 P.M. the first child was delivered by the breech. It weighed about 8 pounds; when the breech began to appear at the vulvar opening, there came quite a long delay which demanded interference, the delivery was quick and easy, but the child was dead. The second child was also a breech presentation. After the delivery of the first, the pains ceased for five hours and as there did not seem to be any prospect of them starting again the membranes surrounding the second child were ruptured, a knee seized and extraction performed readily; the child was in a state of asphyxia, but it recovered. This one was more frail than the first, which did not live. Thirteen days after delivery the mother was seized with a severe eclamptic convulsion but there was but one single attack. There was but a slight trace of albumin in the urine and no œdema.

Case 6.—Eclampsia.—Clara, æt. 38; primipara; extremely anæmic. She had but one convulsion shortly before delivery, which was instrumental; child lived. She continued delirious for a long time; her perineum was lacerated, but her physical condition was so poor, being syphilitic, that it did not unite. Her urine was drawn by catheter and found to contain 40 per cent. bulk albumin. She was purged by magnesia sulphate, and given large quantities of Maine Highland water to drink. The urine increased in quantity; its specific gravity lessened, and she left the hospital without a trace of albumin in her urine. Did not return for secondary perineal operation.

Case 7.—Eclampsia.—Clementina, æt. 18; primipara. This was the only fatal case of eclampsia. She came in two days before delivery, suffering with alcoholism and nephritis. She had been a hard whisky drinker. There were two convulsions before delivery, and eight severe ones after. She continued in a state of stupor, alternating with delirium, until she finally died of exhaustion. Labor was induced by Barnes' dilators, and when the cervix was well spread I applied my axis traction forceps and a healthy living child was extracted.

Case 8.—Eclampsia.—Marie, æt. 40; an emaciated primipara; legs œdematous; severe headache; urine 30 per cent. bulk albumin. Taken with an *eclamptic* convulsion about two hours after delivery. They recurred four times. Potassium bromide and chloral hydrate each 15 grains were given. Hot air bath. Two ounces of magnesia sulphate in glycerine and water were given by rectal injection. Highland water, for its absorbent and diuretic action, was given in large quantities. She was also put on a milk diet. Recovery gradual but complete.

Case 9.—Eclampsia.—Emily, æt. 18; primipara; legs very œdematous; has severe headaches and black motes floating before her eyes. Urinates frequently, it is a very dark amber and heavily loaded with albumin. Appetite poor, *tongue natural. Has taken one drachm* of sulphate of magnesia for the past few days, once daily. This has reduced the œdema somewhat and causes two passages daily. Has been constipated; after examining her on her return to the ward for waiting women she had a convulsion, her first. She was then given bromide and chloral, of each 15 grains. First convulsion at 12:30, noon; second at 1:40 P.M., and third at 2:40. Barnes' bags introduced and labor brought on; delivery instrumental. She was given hot baths and placed on a milk diet and Highland water, and made a rapid recovery; child healthy.

Case 10.—Eclampsia and Amaurosis.—Delphine, æt. 16; primipara. Shortly after entrance at 3 A.M., was taken in eclamptic convulsions. She had four attacks before four A.M., when I saw her and delivered instrumentally. She had been given bromide and chloral, 15 grains each, but in spite of that and hot baths had attacks every hour until eight A.M., when a hypodermic of morphia $^1/_4$ grain was given. She then began to sleep and perspire somewhat. At eight P.M., she had three very severe *attacks*, she was *then given* two ounces of magnesia sulphate by rectal injection, which caused a good evacuation, although she had been taking laxatives, and there were no more convulsions. The giving of sulpl [illegible] by injection is a very useful procedure, [illegible] of coma, when they cannot swallow. The patient was plump and strong. Her urine was drawn by catheter and found to contain 50 volumetric per cent. albumin. After coming out of the convulsion she was blind and remained so for two days, when her sight was gradually restored. She was put on Highland water, and the first two days drank over a gallon. The albumin persisted for a few days, and then completely disappeared. Beef solution was given for the hydræmic state of the blood, and the Highland water for its diuretic property and to assist the defective elimination of urea and for its good effect on the circulation.

Case 11.—Eclampsia.—Minnie, æt. 23. Admitted to the delivery room of the hospital with cervix well dilated. Normal presentation. In about half an hour she was noticed to be in that nervous state that precedes the eclamptic seizure, the bag of water was ruptured and in a few moments after some strong pains she was delivered of a *healthy infant.* The delivery took place at 12 M. She then slept until 3 P.M., when she had an elamptic seizure of considerable violence; before 8 P.M. she had five attacks. Urine 10 volumetric per cent. albumin.

Treatment.—When the nervous symptoms were noted she was given ten grains each of potassium bromide and chloral hydrate, which caused her *to sleep for nearly three hours.* The eclamptic seizure was preceded by an attack of vomiting. After the attack she was given a rectal injection of magnesia sulphate in a small quantity of water. The bowels were well evacuated, and the urine drawn by catheter. She was placed on Highland water in large quantities, and after a time her splitting headache and nervous twitching disappeared and the urine became normal.

Case 12.—Christine, æt. 23; primipara; acute puerperal nephritis. For about three weeks before labor limbs œdematous, which extended above the abdomen. *Has had very* sever[illegible] urine on examination 50 volumetric per cent. [illegible] ore labor came on, was in a ne[illegible] eclampsia; she was given brom[illegible] each, but did not sleep; labor pains started at 4 A.M., and at 9 A.M. she was delivered *of a healthy infant, without convulsions. On the second* day after delivery she had severe abdominal pains, probably due [illegible] h turpentine stupes relieved; her [illegible] and had 33 per cent. bulk albumin. On the third day after delivery she had considerable diarrhœa.

Treatment.—Magnesia sulphate and Highland water. She states that when she takes the water, the pain in the abdomen and back is relieved. The pulse kept at 160, and temperature ranged from 102 to 103½. Lochia normal. Both mother and child did well.

Fig. 2 and 3 are from photographs of the front and back of the left hand of a child two days old; *it* was *perfect in* all other respects. The thumb was of normal size, but the fingers were without either bone or cartilage. The mother gave a history to the nurse of a maternal impression.

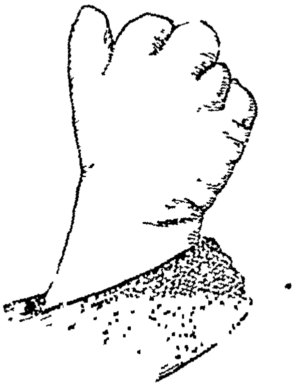

FIG. 2.

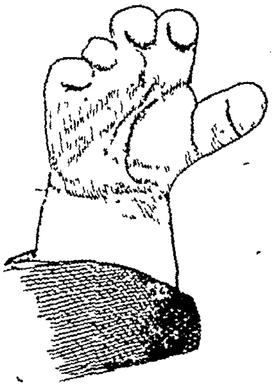

FIG. 3.

Case 12.—Twins; patient æt. 36; v-para; labor began at 6 P.M.; at 3 A.M. was delivered manually of the first child by the breech; the delivery was immediately followed by a placenta, which apparently belonged to the first child. The pains continued very strong and the second child was very soon delivered by vertex *presentation,* the *body* being *extracted manually.* This child was found asphyxiated, but under artificial respiration, counter irritation, etc., it was soon crying loudly; after the second child's cord was cut *it* was found to belong to expelled placenta. The other placenta was removed manually. In the first hundred cases there were four cases of twins and two of these labors were primiparous.

No. of cases, 4; both males, 2; both females, 2; one of each, 0. Of the last pair, one child was dead and macerated, the other only lived two days. In two cases *the* placenta was double and in the other two it was single, but all of them had two amniotic cavities. There were no cases of mastitis *in* the hospital and the application of the breast binder is not used as a routine measure.

There were two cases of spurious pregnancy, both detected on examination immediately after admission. There was one case of *induced labor* at eight months for puerperal eclampsia, both mother and child did well. There was also one case of antipartum hæmorrh [illegible] aged 25, due to shortness of the cord; There were three (3) cases of placenta previa marginalis; in *none of them* was either mother or child lost, and *in none* was the hæmorrhage very severe. In the last hundred cases there were but five applications of the forceps. It was applied twenty-eight times.

Podalic version was performed six times. There were four cases of face presentation; two of them were delivered by natural efforts, and two by the forceps; all the children lived. The youngest patient was 13 years old, there was another not quite 15. The labors of both were normal. There were four cases of footling presentation. No cases of postpartum hæmorrhage that could not easily be controlled.

There was one case of cephalhæmatoma, which enlarged considerably every time the child cried. The labor was easy and the os not rigid. The cranial bones were fragile and the fontanelles large. There were no cases of transverse presentation.

776 Madison Ave.

ON April 26, 1892, Professor James Tyson presented his resignation as Dean of the Medical Faculty, University of Pennsylvania, to take place with the termination of the business incident to the session of 1891–2.

PULMONARY CONSUMPTION:—ITS DIETETIC AND REGEMINAL MANAGEMENT.

Read by title in Practice of Medicine, at the Forty third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY EDWARD F. WELLS, M.D.,
OF CHICAGO.

Pulmonary consumption, the greatest enemy of mankind, is not an incurable disease. However, if the unfortunate subject of this disease is to be given an opportunity to escape the fate of the majority he must be surrounded by favorable conditions and must submit to certain necessary rules and regulations. I deem it an essential preliminary to success that there should be a happy combination of interests and hopes between patient and physician. The patient should be candidly informed of the nature of his malady; of its varied and tedious course; of its leading symptoms and complications; of its dangerous character; of the possibility of a cure and of the necessity of his exercising to the utmost his powers of patience, hope and confidence. On the other hand the physician must have a wide, varied and exact knowledge of medicine in general and of phthisis in particular; he must know and believe that the disease is curable; he must be kind, considerate, resourceful, hopeful and enthusiastic and, above all other qualities, he must be able to transfer his convictions, enthusiasm, and hopefulness to his patient. That this mutual confidence may be obtained and retained, week after week, month after month and year after year, until at last the victory is won, or defeat has been suffered only after every point has been stubbornly contested, requires a most profound knowledge of human nature and the highest qualities of the physician.

One of the most striking features of consumption is the progressive loss of body weight. In the presence of advancing local affection this is so constant that it affords a very accurate index of the progress of the case. Experience has abundantly proven that in a great many cases it is possible to stay the waste of tissues and even to cause the patient to gain in weight by giving careful attention to the diet, and that under these circumstances the pulmonary trouble is held in abeyance and the local lesions have a tendency to heal. This being the case it is evident that the subject of feeding our tuberculous patients is one of prime importance and worthy of the most careful consideration.

Anorexia and defective powers of assimilation are present in those cases in which the stomach and intestines, including their adnexia, are affected by organic disease. Loss of appetite is also a prominent feature in many cases during the height of a febrile attack, and in a certain proportion of patients without any obvious cause. However the rule is, especially in the earlier part of the attack, that the patient has either a good appetite, with moderate capabilities of assimilation, or he can receive, digest and assimilate liberal quantities of food, although he may have no desire for it—there being a state of apathy rather than one of disinclination. It is in this last and largest class that we are able to utilize our knowledge of dietetics to the greatest advantage, and that this paper may not be unduly extended my remarks are confined, in the main, to this class of cases.

Foods which contain nourishment in the most concentrated form should constitute the basis of our dietetic management. In order, however, that the best results may be attained these must be accompanied by properly selected adjuvants, correctives and —padding. By the last term I mean certain bulky articles of food having but little nutritive value, but which are necessary for the greatest digestive and assimilative activity. For many years I have discussed this subject very freely with my patients, inquiring into their preferences and sensations and obtaining their opinions and estimates, and the following diet table is the result of my experience. In practice it is suitably modified to meet the surroundings and other exigencies of the individual case for which it is prescribed:

MENU.

On Rising, 6 A.M.

Hot milk and Vichy. Hot meat broth.
Milk tea, tea made with milk.

Breakfast, 7 A. M.

Rare steak or loin chops. Mutton chops with fat.
Bacon or ham, with fat.
Eggs.
Potatoes, Saratoga chips. Fried mush.
Toast, with cream or butter,
Oatmeal, wheaten grits or rice, with cream.
Fruit.
Coffee or coca, made with rich milk.

Lunch 10 A. M.

Milk. Egg nogg. Meat broth.
Stale bread. Zweiback.

Dinner, 12:30 P. M.

Beef, mutton or chicken broth. Oyster or turtle soup.
Raw oysters. Raw clams. Fish.
Poultry. Roast beef or mutton. Game.
Potatoes. Cauliflower. Green peas. Tomatoes.
Celery. Pickles.
Asparagus. Lettuce. Spinach.
Stale bread. Graham bread. Corn bread.
Baked apples with cream. Ripe fruits.
Custard pudding. Pie. Cake.
Milk. Milk coffee.

Lunch. 3:30 P. M.

Milk. Koumyss. Clabber
Beef tea. Thick soup. Meat broth.
Ham sandwich.

Supper. 6:30 P. M.

Thick meat or fish soup.
Raw oysters. Cold meats.
Stale bread. Crackers. Graham bread.
Meat jellies. Neufchatel or Cottage Cheese. Fruit jellies.
Fruit. Ice cream. Cakes.
Milk coffee. Milk tea. Egg nogg.

Lunch. 9:30 P. M.

Hot milk. Beef tea. Meat broth.

To this list may be added such other foods and drinks that the appetite craves and are found to agree. Any article of diet which the experience of the patient has shown to be detrimental is to be omitted.

Food should be taken in as large quantity as possible. At each lunch from a half-pint to a pint of liquids should be taken, and at each of the three principal meals an equal quantity of milk, or of coffee, tea or cocoa, made of rich milk and cream, should be ingested. There is no objection to changing the dinner hour to 6:30 P. M., and taking a midday luncheon equivalent to the supper as prescribed. Meals should be never hurriedly taken and should be always accompanied by cheerful conversation. Eating should be made one of the principal objects of the patient's life.

The diet should be varied to meet special indications or the patient's desires. If there is little or no fever, and if starch, sugar and fats are well borne, foods containing these principles in abundance should be freely employed. If there is much fever, or if there is apathy or antipathy toward eating the diet should be composed, mainly, of animal foods and very concentrated nourishment, with fresh fruits and vegetables.

If there is a tendency toward flatulent distention of the stomach or bowels after eating, bread and other farinaceous articles of food should be taken sparingly. If the bowels become constipated, fruits, coarse vegetables, corn or graham bread should be largely eaten, and if diarrhœa supervenes avoid the kind of foods above mentioned.

At the very beginning of treatment the patient should be impressed with the great importance of certain hygienic and regimenal regulations. These should be fully discussed with him and he should be made to understand the reasonableness of the rules prescribed in order that his hearty and intelligent co-operation may be secured. The peculiarities of the patient must be fully weighed but the following points I consider with every patient.

Consumptives are usually persons who have formed strong attachments for their home, family and friends and do not readily adapt themselves to changed surroundings. For this reason home is the best place for the majority of these patients. This does not apply to the comparatively small contingent of phthisical patients who are always in touch with their surroundings and who are natural travellers. With these travel, change of scene and climatic treatment may be considered, but a change of residence should not be undertaken without thoughtful consideration and special advice from the medical attendant.

The residence should be exposed to sunshine and sheltered from cold and raw winds. The rooms should be well ventilated, free from draughts and comfortably warmed and furnished. The home should be entertaining, pleasant and cheerful. The patient should sleep alone.

Pleasurable exercise, such as riding, boating, walking, traveling, games, etc., and non-exhausting employment which interests and does not expose to deleterious influences are beneficial.

At frequent intervals the patient should practice forced breathing, both inspiration and expiration. As a measure of the ærial capacity of the lungs he should count aloud as many as possible without taking breath.

The clothing should be light and comfortable. That next the skin should be of wool and of fine texture. In cold weather the clothing should be sufficient to prevent chilliness, and the chest should have extra protection.

Once or twice weekly the patient should have a hot sponge or tub bath. The surface should be quickly rubbed to a glow and enveloped in warm woolen garments. The bath-room should be comfortably heated.

Should night-sweating supervene, bathe the surface with very hot water or vinegar and, after drying, rub with flour, starch or other absorbent powder.

Twice a day there should be applied to the surface of the chest a stimulating linament, composed of equal parts of turpentine and oil of hyoscyamus or oil of sassafras. Mustard plasters and hot applications may be made use of for the relief of local pains. These failing to give relief, small blisters may be employed.

The cough should be restrained as much as possible and endeavors made to expectorate with every effort. A dry, irritable cough, without expectoration, should be held in check by proper remedies.

The sputæ should be received in a cup containing a quantity of moist absorbent and antiseptic material. The contents should be removed once or twice daily and the cup cleansed. Moist antiseptic cloths may be substituted for the cup. The cloths and the contents of the cup should be burned.

Catarrhal colds should be avoided by every known means and if they occur they should be treated with the utmost care and the treatment continued until the disappearance of every trace. The patient should consult his physician at once upon the appearance of new symptoms, the significance of which may be unknown to him.

The patient should observe and record carefully his condition from day to day upon suitable blanks; such records afford information of the greatest value in formulating prognoses and lines of treatment. He should bring them along when he consults his physician. "With careful instruction an intelligent patient may become," to a limited extent, "his own observer and, to a certain extent, his own medical attendant" and to his advantage.

163 State St.

DOMESTIC CORRESPONDENCE.

Laboratory Work in Medical Schools.

One of the most interesting papers presented at Detroit was Dr. Vaughan's earnest plea for more laboratory work in our medical schools, read before the Association of Medical Colleges. The course of study is now lengthened to four years, and the term of nearly all medical schools is now more than six months. There is time for this work. The European medical education is superior to the American only by the facilities which it offers in laboratory instruction. It is for histology, pathology, bacteriology, clinical diagnosis and multiple dissections that our young medical men go to Germany.

The method of instruction at the bedside is recognized by educators as essential. This is only possible in large cities. The study of chemistry, pharmacology, histology, pathology and surgery in the laboratory could be as perfectly carried out in a village of ten thousand inhabitants as in a city of a million. Yet the laboratory method of teaching has not been undertaken in the majority of medical schools.

In speaking of proposed laboratory work, the writer was informed by an old college man that the time for laboratory instruction had not come, and that this was the age of clinical teaching. This is a position that can not be maintained. The universities are establishing courses preparatory to medicine and leading to the B. S. degree, in which laboratory work is a prominent feature. The men who have completed these courses are going into our medical schools and they are loud in their denunciation of the antiquated manner in which medicine is taught. They are forcing attention to the methods of instruction and proper sequence of studies and some of them are now able to demonstrate the more rational ways of teaching in their own class rooms.

It has been asserted that our average medical student can not and will not do laboratory work. This is an error, as the teaching of chemistry during the past ten years, at least, has shown. If any further evidence is needed, the writer may be allowed to introduce his personal experience at the College of Physicians and Surgeons, of Chicago. Last year twelve hours a week of laboratory work was added to the two junior years. At first the students complained. A few rebelled. They were held firmly to their work and at the end of the year all dissatisfaction was gone and a new spirit, the scientific spirit, pervaded these classes.

The expense of laboratory teaching has been urged to bar it out of our schools. It is a fact that laboratory work is expensive. The proper housing of the laboratories cannot be much short, for the average class, of $500.00 each. Thus the laboratories for a school of one hundred students ought to cost not far from $50,000.00. This is in addition to lecture rooms and clinical facilities. The equipment would be a variable quantity and might be as low as $50.00 per each student or as high as $200.00. Allowing $600.00 as the capital invested, the interest alone on this amount, at six per cent. would raise the expense to each student $36.00. Add to this the material consumed and the expense for building, equipment and material cannot be short of $50.00 for each student each year. Admitting that the expense of laboratory teaching is great, it is no argument against its adoption. Students are willing to pay for what they get. Those schools that offered clinical facilities ten years ago secured the large classes and the large fees. Those schools that now offer laboratory instruction will secure an increased attendance.

The fact that most of the lectures are given in our medical schools without financial compensation or for a nominal salary makes it possible for many medical schools to hobble along without an income of any size. The adoption of laboratory instruction means the payment of salaries to laboratory instructors. There is a feeling among young medical men that it pays to give a surgical clinic before a class of students but that there is no return for eight or ten hours laboratory work each week before the same class. The writer believes that this is a mistake. It is a fact that laboratory work requires more time and study on the part of the teacher than any other form of teaching. There are very few men in medicine to-day who can properly conduct a laboratory exercise. But for the capable it will pay.

The loose manner in which the business of many of our medical schools has been conducted would be disastrous if they had large laboratories. Like the factory, the laboratory must have an accurate and centralized government, a simple and rapid system of book-keeping and the most conscientious scholastic supervision.

The results, in the productions of scientific medical men, by the introduction of proper methods of medical study, almost any experienced educator would be willing to predict. The quality of medical culture will be increased The medical schools will attract a larger proportion of college bred men. The lecturers will cease to cram their students with the pap which has so long been doled out to them and the scientific spirit will permeate the post-mortem room and the clinical amphitheatre, and last of all the pages of our medical literature will cease to be disgraced by pages worthy the age of witchcraft.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

To answer the many inquiries of the gentlemen who were present at the operations at Harper Hospital, during the late meeting of the Association, I wish to state that all cases of laparotomy recovered. In the first difficult case of Dr. Joseph Price, of Philadelphia, where he predicted that a fecal fistula might develop, this actually took place, but by keeping in the glass drainage tube for three days and then substituting the rubber tube and also by keeping the tract perfectly aseptic with hydrogen peroxide and covering the wound with bi-chloride gauze, the fistula gradually closed up, in the course of three weeks, and the patient is now about, walking, riding, etc.

The second case where a hole was made in the intestines, which had to be sewed, made a rapid and uneventful recovery.

The case operated upon by Dr. Ross, of Toronto, with the most firm and extensive adhesions recovered rapidly, and left the hospital just two weeks after the operation.

The case operated upon by Dr. H. W. Longyear, of this city, also recovered, union throughout by first intention.

My four cases also recovered without any bad symptoms. This includes the last very difficult case of vaginal hysterectomy. For cervical cancer, the woman being ten weeks pregnant, the clamps were removed in forty hours; with difficulty the woman was kept in bed until the eighth day, on the tenth day she walked about, and on the twelfth day when I arrived at the hospital I was told that the woman had gone home, one hundred and fifty miles from here, saying she was homesick and was now perfectly well. I received a letter yesterday from there stating that she was apparently perfectly healthy. Yours truly,

Detroit, July 16, 1892. DR. J. H. CARSTENS.

The New York Medical Journal and the American Medical Association.

A lengthy comment appears in the editorial columns of the *New York Medical Journal*, upon the affairs of the American Medical Association. To the reader, who has kept a close eye on the editorial columns of this journal, the present article is no surprise; from the fact that it is patent to the most casual observer, that there are a few members of our profession who regard the American Medical Association in the light of the old Romans, who were bound that Carthage should be destroyed.

What appears to give the editor a large scope for finding fault is the report of the committee on the Section on Dermatology which appeared in the JOURNAL of the Association I mention, and which the editor of the *New York Journal* comments on as follows:

"It does not seem that the committee struck the keynote of the trouble. Verily the medical profession has progressed since the organization of the American Medical Association, and features of that day and generation are not matters of overwhelming interest to-day. As long as the Association devotes as much of its time to the discussion of ethics, carrying it on in such a manner that the report reads: 'The excitement was so intense and the discussions so heated that we deem it prudent to omit them,' so long will the more prominent members of the American medical profession refrain from attending the meetings."

It is well that the reader takes particular note of the last two lines, from the fact that it is generally supposed that the American Medical Association contains a large proportion of the prominent members of the profession, excepting the editor of the *New York Medical Journal.*

The following paragraph brings prominently into view the professional patriotism of the editor of the *New York Journal*, which if it were true, nobody would find fault with.

"Contrast the program for the coming meeting of the British Medical Association with that of the recent meeting of our Association! And not only for this, but for many more years has the former been infinitely better. It works scientifically; ethical discussions are as alien to it as they are within a first class scientific organization of any sort."

Two years ago, the writer attended a meeting of the [illegible]

or a

ish Medical Association, and knows from personal observation that the above statement is not true in every particular. He was afterwards informed while in London, that it was a certain Birmingham doctor's "show" and that the animals were not all well trained.

Permit me to quote the last paragraph in the editorial, because it points out the animus of the whole article.

"Insistence upon discussions has resulted in the organization of the various special societies and of the triennial meeting of a general congress of all these societies. Some day the American Medical Association will realize that tomes on ethics will not be looked upon as its legitimate work; and we hope this awakening will not come too late to enable the Association to regain the ground it has lost."

It will be readily perceived that this article written by the editor of the *New York Medical Journal* was not presented to its professional readers in the interest of the American Medical Association, but on the other hand for the benefit of the special societies, which do not have a place within their organizations for the general practitioner; neither do these organizations have any sympathy with him, only when he supplies them material, as the jackal does the lion.

There is no organization from the Atlantic to the Pacific, from the river St. Lawrence to the Gulf of Mexico, but the American Medical Association, where the general practitioner can make himself at home, can discuss medical questions with, and receive information from the best medical talent in this broad land. The founder, Dr. N. S. Davis, of this great American Medical Association will live in the minds of the profession, when its would be destroyers have long since been forgotten. J. F. JENKINS, M.D.

Tecumseh, Mich., July 15, 1892.

A Necessary Correction.

Southern Surgical and Gynecological Transactions, Vol. IV, page 163.—"Dr. George A. Baxter, Chattanooga, Tenn.:

I declare myself positively in favor of early operation in these cases, but I want to relate a case such as will be, and is used against it. A gun specially loaded for the object was discharged at a distance of less than twenty feet, and one negro had shot another in the back, seventeen balls by actual count entering the right kidney. One of them was detected underneath the skin, further around to the right side; and one, evidently striking some portion of the spinal column, was detected in the clothes. *Fifteen balls, however*, could not be found by those gentlemen first having the case in charge. The man came under my care six days after the injury, with no indication of peritonitis; but he had at that time an enormously enlarged liver and stomach. He had had hæmoptysis more or less since his injury, and the symptom that brought me into the case was hiccough, which lasted six days. Now, gentlemen, I did not probe for these balls. I did not operate, since what mischief was to accrue had done so already, and an operation could accomplish nothing at that late date. The negro had, however, I am persuaded, perforation of stomach, liver, and diaphragm. That negro got well, and is a perfectly well man to-day after two months' sickness. At no time had he a temperature above 100½°. He had had constant vomiting of bile for nearly three weeks, and he had a little discharge of blood occasionally for a month from his stomach. The hiccough gradually subsided only after six days. These are the kind of cases that will be urged against operative interference, etc."

Above is quoted a case reported by me in the last meeting of the Southern Surgical and Gynecological Society, in the [illegible]f debate, which from slight error in the report over[illegible]y me in the proofs, perverts my meaning so grossly as to make the case ridiculous, as well as rob it, by seeming exaggeration, of the scientific interest. I therefore call attention to it in THE JOURNAL previous to a contemplated correction before the Society, which does not meet until next November, for the satisfaction of several excellent surgeons who desire the real case, remarkable enough in its entirety, without the semblance of exaggeration. The sentence, "A gun specially loaded for the object, was discharged at a distance of less than twenty feet, and one negro had shot another in the back, seventeen balls by actual count entering the right kidney," should read *"the region of the right kidney."* That this was so intended is evidenced by the next sentence which says, "One of them was detected underneath the skin further around to the right side," and "one striking the spinal column, was detected in the clothes," which could not possibly have been the case if they all (17) had entered the kidney.

Having explained myself on this point, I am prepared to go further now and explain more fully than this report gives, a case which seems to have attracted a good deal of attention, the facts I desire to add making more plain my *probable*, not positive, diagnosis of liver, stomach, and diaphragm injury or perforation.

The negro had for the space of about three weeks, frequent daily vomiting of bile, this mixed occasionally with slight quantity of blood for first few days, as reported by him. He had an enormously distended liver, resulting in an abscess which pointed high up in front, which abscess was opened by me in the presence of Dr. H. Berlin, of this city, and from which was discharged pus and bile. No ball, however, was found. Is not this sufficient data for the *probable* diagnosis of perforation of liver by one or more of the lost fifteen balls? He had distinctly diagnosed, not by me alone, but by others who saw the case, also a greatly enlarged stomach, with almost constant vomiting, generally of bilious matter, but by his own report, mixed with blood for a few days. This last I did not see as he came under my charge on the sixth day—but in addition thereto, blood by rectum, which I did see and which was also seen by Dr. Berlin. Upon this data am I not right in diagnosing a *probable* perforation of the stomach by the same or another of the lost fifteen balls?

Now for the *probable* perforation of the diaphragm. I have stated that the symptom that called me into the case was hiccough, which lasted six days, gradually subsiding. It is true that here there are other reasons and forces to account for this symptom besides injury or perforation, but considering its persistent character, the fact that the direction of the balls were known, both by the one which still remained under the skin higher up and to the right side, and the stomach and liver symptoms, both of which pointed strongly to perforation, and the further fact, which has not been before stated, except in a report to our local society, that the negro was running in a more or less stooped condition, making positive the direction of the balls inward and upward; and the almost certainty, as it seemed to me that two of the balls had entered the abdominal cavity, to injure the liver and stomach, made the probable diagnosis of injury or perforation of the diaphragm the most probable and easiest explanation of the hiccough. This was all that was claimed, all that could be claimed short of the dissecting table.

The low temperature throughout this case is a positive observation. What it was before the sixth day I am unable to say or find out, for the gentleman who had charge of the case until that time kept no record, but after the sixth day it never exceeded 100½°, notwithstanding a probable perforation of the liver with formation of abscess of the stomach, with bloody vomit and bloody discharges, and notwithstanding a hiccough that lasted six days. The tests were made with a well proven Hicks' thermometer. This man was seen during his illness by Drs. Boyd, Ellis, Holtzclaw, Berlin, Rathwell and Cobleigh, and was afterwards presented to the local society with his full history, for examination, and the same probable diagnosis given, and any one of them are sufficiently familiar with the case to certify to the correctness of the statement given. This explanation is given in full for the benefit of several worthy gentlemen who have seemed particularly interested in the case, and I believe all points are elucidated upon which inquiry has been made. I would not have obtruded it again upon the public otherwise. G. A. BAXTER, M.D.

Chattanooga, Tenn., July 7, 1892.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JULY 23, 1892.

BY-LAW IV OF THE AMERICAN MEDICAL ASSOCIATION.

The Publication of Papers and Reports.

No report or other paper shall be entitled to publication in the volume for the year in which it shall be presented to the Association, unless it be placed in the hands of the Board of Trustees on or before the first day of July. It must also be so prepared as to require no material alteration or addition at the hands of its author.

Authors of papers are required to return their proofs within two weeks after their reception; otherwise they will be passed over and omitted from the volume.

Every paper received by this Association and ordered to be published, and all plates or other means of illustration, shall be considered the exclusive property of the Association, and shall be published and sold for the exclusive benefit of the Association.

The Board of Trustees shall have full discretionary power to omit from the published *Transactions*, in part or in whole, any paper that may be referred to it by the Association, or either of the Sections, unless specially instructed to the contrary by vote of the Association.

A BILL FOR THE REGULATION OF EXPERT TESTIMONY.

At a recent session of the Minnesota State Medical Society, DR. B. J. MERRILL, of Stillwater, chairman of the Section on Medical Jurisprudence, directed his arrows at the prevailing abuses of the so-called medical expert. He submitted the subjoined bill for the consideration of the Society, and requested that formal action be taken looking to the correction of prevailing abuses by some form of conservative legislation.

A BILL TO PROVIDE FOR THE APPOINTMENT AND PAYMENT OF EXPERTS.

Be it enacted by the Legislature of the State of Minnesota:

SECTION 1. In all cases pending in the courts of this State, civil and criminal, before or at the time of the trial of said cases, the Judge of said court, when it is made to appear to him that the appointment of experts upon medical, scientific or mechanical questions is desirable, may appoint such experts to examine into the subject matter in controversy, said experts so appointed to be selected in reference to their impartiality between the contending parties; the number of such experts in each case to be fixed by the court.

SEC. 2. In all cases where experts are so appointed, the court is to fix their compensation, and in all criminal cases direct the payment of the same in the same manner as witnesses on the part of the State are paid; in all civil cases the amount so fixed and determined by the court shall be taxed as disbursements by the successful party.

SEC. 3. The court may order such experts to examine into any medical, scientific or mechanical question, and after such examination to testify in court in reference thereto.

SEC. 4. The testimony of said experts so appointed by the court, shall be *prima facie* evidence of the statements and conclusions as to the questions in reference to which said testimony has been given.

SEC. 5. The court may also fix and determine the amount to be allowed such experts for and on account of any medical, scientific or mechanical examination, analysis or test, which the court may deem advisable to have made, and direct the payment thereof, or permit the taxation thereof, as costs as hereinbefore provided.

An eminent jurist, in writing upon the question of evidence, divided unreliable witnesses into three classes, to wit: liars, blank liars and medical experts. Upon reflection we frankly confess our inability to successfully controvert the conclusions of the writer. While under ordinary circumstances we would vigorously object to being in any manner associated with liars, we are unable to disassociate the average expert from the unreliable witness. Until present customs cease both upon the part of the lawyer and the doctor, the allegation of JUDGE STORY must stand unrefuted.

We freely admit that abuses exist and that reform is imperative.

The existing conditions, however, are quite as much the product of the lawyers' shortcomings as those of the doctors or medical expert. It matters not how sincere the expert may be, the attorney is not disposed to permit full and unbiased expression from the lips of the expert. He will only elucidate such data as have a favorable bearing upon his side of the case. The expert is engaged by the attorney and paid by his client. This is wrong. He should be engaged and paid by the Court, and be wholly at liberty to freely express his views. In the direct examination upon either side the questions are skilfully drafted and most misleading when scientifically applied. Fragmentary sentences from standard authors are frequently read to the witness that may have a germane bearing, and the expert compelled to answer the question by yes or no. We are not mitted to explain our position *in extenso*. comes the expert for the defense with a d ent solution of the same question and the result happens. The jury fails to consider pert evidence at all, and not infrequently own interpretations upon questions they know little or nothing of.

In view of existing practices we believe the representatives of the profession of law have been somewhat captious in their very free criticisms of medical experts. It was certainly very proper and politic in the Minnesota Society to remand the consideration of this bill to a committee of five, the majority of whom were lawyers. The proposed bill will in our opinion bear close scrutiny. It is the best draft of a bill upon this question we have examined. This is preëminently an era of medical legislation, and the occasion opportune for work in this direction. The profession will render all the assistance possible, as they will not look upon the commercial side of a question of this character. Coming as it does from Minnesota, it carries with it prestige. The profession of this State possesses the faculty of crystallizing public and professional opinion and bringing about their reforms in a most efficient manner. The bill has not the provision for the appointment of the permanent board of experts that is customary in Europe, but provides for the selection of men by the Judge as occasions may arise. It is not reasonable to fear a monopoly, as the Judges will in all probability select men representatives of the specialties in metropolitan communities, and in communities remote from centers of population they will of necessity select the competent, all around general practitioner. If this bill were to become a law, the court procedure would be quite different from that prevailing in monarchial forms of government. The expert could not shield himself behind his written opinion. Our Constitution, in criminal cases at least, provides that the accused criminal may, either in person or by attorney, directly cross-examine all witnesses. The bill would make the expert accountable to the Judge only, who is the true representative of justice. It will, we believe, subserve the best interests of the public and promote justice.

In civil cases the amount of litigation would be greatly lessened. The number of "railway spines" would lessen by at least 99 per cent. The pathology of spinal injuries would be less ambiguous and contradictory, and more in keeping with common sense. The rights of corporations would be less frequently outraged, and the profession greatly elevated in the estimation of a critical public. The profession will await the action of the committee with interest, and trust they may prove themselves equal to the exigencies of the occasion, and that their motto may be *pro bono publico.*

The one-hundred and twenty-sixth annual meeting of the Medical Society of New Jersey took place at the United States Hotel, Atlantic City, N. J., on Tuesday and Wednesday, June 28 and 29, 1892.

CHOLERA.

The wonderfully increased facilities for rapid transit, and inter-communication between nations makes the presence and spread of cholera in foreign countries at this time, a very serious menace to the people of our own land.

For a number of years we have solaced ourselves with the comfortable belief that modern sanitary science has effectually barricaded cholera from Europe and America. The present condition of famine in Russia, with its consequent train of pestilence, makes the entire population of vast regions easily susceptible to this additional scourge, while the increased immigration from that country to our own affords the health authorities of our States and cities a good and sufficient cause for increased vigilance, and the adoption of necessary quarantine measures.

The many water-ways that furnish scores of towns and cities with their sole supply of water should, so far as possible, be freed from contamination and pollution.

The increase of enteric disease in many localities at this time. is a sufficient reason for investigation as to its cause and consequent removal.

The near approach of the time when hundreds and thousands of people from all parts of the habitable world will visit this country and focus to this city, should force upon the municipal authorities of Chicago, a realization of their responsibility in this direction, and compel a much more vigorous effort than is apparently being put forth, to not only sweep, garnish and put in order every sewer, street and alley but to give the city an overplus of unpolluted water for every household purpose.

In case the germs of cholera should reach this city, the conditions for a spread of the disease to the direst epidemic proportions are singularly favorable.

That it should be necessary, month after month, to boil and filter every pint of water that is used for drinking purposes in a city of more than a million of inhabitants, is a scandal of monumental proportions upon the city government.

This condition of affairs is not only well known at home, but is now thoroughly noised abroad, to the very great detriment of World's Fair interests.

The men of conceptive minds, of enterprise and ability are here and could speedily change most of the disparaging conditions to which we have directed attention. A diversion of thought from a contemplation of unparalleled enterprises, to the more homely one, of preparing to give a cup of pure water to every stranger that visits the city, will soon do the work. We are patiently waiting for a manifestation of the workings of the minds of some men in this direction, and will be glad of an opportunity to tell the world through our pages that the conditions to foster an epidemic of cholera or any other enteric disease do not exist in the World's Fair City.

EMULSIFIED VACCINE LYMPH.

An interesting review of the present status of vaccination has appeared in the *Medical News*, May 14, by the pen of DR. JOHN V. SHOEMAKER. No country has, in recent years, given a more scrupulous attention to the production of lymph than Prussia. DR. SHOEMAKER has been supplied by the Berlin Institute for Animal Vaccination, which is in the charge of DR. PISSIN, State Councillor of Health. This institute was established in 1865, and DR. PISSEN has been a contributor to the literature of small-pox prevention since 1868. The lymph-products of DR. PISSEN have become so favorably known in the country of their origin, that they are exclusively employed as the material for vaccination and re-vaccination in the German army. The lymph is obtained solely by calf-to-calf vaccination. The animals are subjected to rigid examination, and every discoverable source of impurity and contamination is carefully eliminated.

"This lymph is put up in two forms. First, the *pure lymph*, which is a product of constant and unvarying activity, obtained directly from the calf. It should be used in a comparatively fresh condition, that is to say, within from four to six weeks after the date of preparation. This is a beautifully limpid fluid, almost as colorless as water, and is enclosed in hermetically sealed glass tubes. The *emulsified lymph* is prepared from the pure material by a special process. This preparation is a little thicker than the pure lymph, and is slightly turbid. It is equally effective, is far more stable, and retains its power for an indefinite period if the tubes are kept in a cool place. For many years, it is claimed, the results with DR. PISSIN'S lymph have been 100 per cent. of successes in primary vaccinations, and from 80 to 90 per cent. in re-vaccinations. The materials are put up in tubes of different sizes, containing a sufficient quantity for five, ten, or twenty-five vaccinations."

Both forms of the lymph have been used by DR. SHOEMAKER. He says that his success has been uniformly good and he can report that "the claims made for it are borne out by my own experience. In every case the vaccine lesion was perfectly typical and unattended by any unusual local or constitutional phenomena. These tests exemplify not only the efficiency of the preparation, which is, of course, the chief point to be considered, but also incidentally the preservative influence of the sealed tubes—for the fine lymph, which is the least stable, did not reach me until eight weeks after it had been received by the English agent, and it must have been at least a few days old when it first came into his possession. As regards fixity, therefore, it must be regarded as the equal if not the superior of lymph dried upon points. The emulsion that I employed was a fresher sample, being about two weeks old. Both varieties were entirely efficient."

The lymph should be applied as follows: "The skin is cleansed with soap and water at the spot selected for the operation, and wiped quite dry. The extremities of the tube are then broken off, and a sufficient quantity of the lymph blown upon the skin, preferably upon four separate places. Then with a blunt lancet, or darning-needle, previously disinfected by passing through the flame of a spirit-lamp, the lymph is scratched in, care being taken not to abrade the epidermis, any effusion of blood being undesirable. The part should be allowed to dry before the clothing is readjusted, and should not be washed again for a week." Certain of DR. SHOEMAKER'S friends, to whom he gave a share of his lymph, have informed him of successes equal to his own. A single point of criticism is raised in respect of the mode of application, but not of the article itself. It is possible that a waste of the fluid may occur in the act of blowing it from the tube; and there may be some want of success in completely resealing the tubes, when their contents have not all been utilized.

EDITORIAL NOTES.

A CLASSICAL QUOTATION WANTED.—The much abused quotation "who shall decide when the doctors disagree" is floating around again. It circulates far too freely and widely, when we consider that it has fundamentally no relation to the medical profession whatever. The original Latin saying, when first coined and used, we all know, when we reflect upon the subject for a moment, dates from a time when medical men were never called "doctors," and when the only "doctors" were the teachers of the Holy Mother Church, the only doctors then were the gentlemen of the cloth, the clergy. And they were all the time at odds with one another—so we are taught to believe—to such an extent that this adage came into being and has held its place a thousand years, more or less. Only by a strange *contretemps* it has been shifted off from the clergy, and medicine has most unjustly been saddled with it. The old Latin saying had in it a reference to the *disipulus*, meaning the theological student, and affected to pity the distraction of his mind, while the holy teachers were engaged in criticising one another. The disputes of the theologians, in those early days, were marked by an earnestness and rancor that far exceeded anything that can be seen in the medical fraternity—even if it be a question of ethics that is up for decision. For these reasons, we propose to ask any classicist who may read our protestations and who knows the proper Latin text and source of this adage to send them to us and thus help in putting the mischievous quotation where it belongs, with the clergymen. Every time that it seems to be necessary we will quote the original in its original setting. Let us all spurn the "misfit" adage.

THE LOUISIANA MEDICAL SOCIETY SESSION OF 1892.—The June number of the *New Orleans Medical Journal* gives an account of the four days meeting at New Orleans, in April last, this being the thirteenth annual session. The time of the second day was largely devoted to the perfection of a new bill to regulate practice, and to provide for a State

Board of Examiners, which will probably be passed by the next legislature. Important and influential committees were appointed in order to aid, in every legitimate method, the prompt adoption of the important measure. The well-known names of Drs. Miles, Logan, Chaillé, Bemiss, Bickham, Matas, Parkham, and McShane are only a small portion of those engaged in the warfare against irregular medicine. Dr. J. B. Elliot, was made president of the Society a second time, despite his personal protestations against two terms. This was done to retain his services in behalf of the proposed act during the renewal of the campaign before the State legislature. The president is given authority to name the delegates to the American Medical Association. There is room for doubt whether this is, or is not, the best method for choosing representatives. We hold that, unless there are urgent reasons to the contrary, a portion if not the entirety of the delegation would better be elected by any given association before adjournment. The President should, of course, be authorized to fill vacancies. We have known the former course to give rise to undesirable allegations.

The members of this State Society are enlisted in strengthening the membership and basis of representation. It is a most worthy undertaking, and we are pleased to mention that one of the members, Dr. W. G. Owens, was given an especial vote of thanks for his success in causing a large number of new members to unite with the body.

Dr. Lemonnier addressed the Society respecting the duty of the members as to ignorant midwifery. There are more deaths of women and children, he believed, brought about by the midwives than by the murderers. He had succeeded in bringing two of these women before the courts, but they had been discharged because there are no laws for the limitation of that branch of practice. He was requested to frame a bill on that subject. The next meeting of the Society will be held in May, 1893, and at New Orleans.

The editorial columns contain an elaborate estimate of the career and character of the late Dr. T. G. Richardson, one of the ex-presidents of the American Medical Association, and they are adorned by a speaking photogravure likeness of the long-time professor of surgery at Tulane University.

Tonic Lotion for the Skin.—It is claimed for the following compound that it tones the cutaneous circulation and prevents wrinkles: Two ounces of spirits ammonia, the same of tincture of camphor, five ounces of coarse salt, one quart of boiling water. After these are well agitated and cold add six ounces of alcohol. To be shaken before using. This is called a "skin tonic" and is both refreshing and rejuvenating.

Vaseline an Undesirable Lubricator.—In *Memorabilien*, Novotmy has given a warning against the use of this substance to lubricate sounds and other vesical instruments. He has twice found this insoluble material serving as a nidus about which a mass of detritus had accumulated or acting as the rallying point of urinary sediment. A very little of the lubricant, left behind each time that a sound is passed, would in time, in some cases, attain to the proportions of a foreign body of appreciable mass. In one of Novotny's cases the quantity of mixed sediment and lubricant amounted to 150 grains in weight.

Chian Turpentine in Cancer: Nine Years' Experience.—Prof. John Clay, of Birmingham, has given in the *Medical Press* his latest views regarding the use of Chian turpentine in cancer. In his article he publishes the leading characteristics of five cases of differing types which serve to show, as he believes, that his remedy is "a palliative agent of no mean value." These five cases appear to have been of a severe grade and their subsequent condition warranted such reports "no recurrence," "excellent health," "well in every respect" and "very active."

He repeats his former plea to put the patient on the use of the Chian drug before the disease has become advanced and has begun to impress itself on the system at large, or to engage vital parts in the vicinity of the organ at first involved.

But even in such advanced cases, he asserts, the drug is competent to allay pain and diminish blood-loss. He has some uterine cases, treated as long ago as nine years, that are even now living and in a satisfactory state of health.

A Chian turpentine patient, he says, when cured seems to have all the latent germs eradicated; the tendency to recur is not apparent. He believes in using the drug as a preparative to operation. If the knife must be used, he would have the patient take the drug for a period of three weeks or longer. And after the operation is performed he would continue the medication for a twelvemonth. He has seen this plan followed in a number of cases during the last six years, and no return of the disease in these cases has been known to him.

His best results from the Chian drug have been obtained in growths affecting the tongue, face and head. If used early, even when the glands of the neck have become enlarged, "a cure may result." When glandular enlargement has arisen, it is his habit to give the drug in small doses, lest sloughs in the vicinity of the great vessels of the neck may be induced by too active medication. Regarding uterine cancer his experience leads him to say that complications, such as extension of the disease to adjoining structures, arise very seldom when the turpentine is employed, whereas they are almost the rule in other cases.

The purity of the drug is of prime importance, according to the author; and imposition is frequently practiced to the detriment of the sick. The preparations made for Dr. Clay, by the Southalls of Birmingham, have the advantages of purity and careful compounding to suit the different classes of cases. Dr. Clay believes, for instance, that the pills are more efficient than mixtures; but in cases of cancer of the stomach and rectum the pills should not be given.

It will often be necessary to inculcate patience on the part of those taking the medicine, and very speedy results should not be promised. Two or three weeks, perhaps longer, may elapse before any changes in the growth are discernible.

Treatment of Fracture of Clavicle.—With the exception of the femur, there is no bone fracture with which the surgeon meets where a shortening so uniformly results as in the clavicle. The testimony of surgeons from Hippocrates to the present time in that however careful the treatment of this fracture, deformity almost always results. The difficulty does not lie in the reduction of the fracture, for as a rule this is very easily accomplished; the trouble we meet is in retaining the reduction sufficiently long for nature to establish an osseous union, even after the parts are properly adjusted the slightest movement of the head, arm, or even the movements occasioned by respiration are frequently sufficient to displace the fragments again to the position they occupied before their reduction.

I would like to call the attention of the profession to a treatment that has proved successful, that is the use of the bone dowel or peg. After reducing the fracture in the usual manner pierce the clavicle with an awl, let it extend from one broken fragment to the other, then insert the antiseptic bone peg completely. The arm and elbow is now suspended in a sling and the arm is confined to the chest either by a few turns of the bandage or a few broad strips of adhesive plaster.

By this method you will not meet with the difficulties met with in the wire suture advocated by Von Langenbeck and the results will be more perfect.

A. S. Kinnaman, M.D.

1920 Euclid Avenue, Cleveland.

BOOK REVIEWS.

The Medical Register of New York, New Jersey, and Connecticut. 1892-3. Published for the New York Medico-Historical Society. Dr. William T. White, editor.

This is the well-known "Green book," as it is familiarly called in New York; so called from the color of its cloth binding, which has been retained for about thirty years. It contains over three hundred closely printed pages, giving information primarily about medical men and institutions. It also touches lightly on other sub-heads of organized work that is contributory to medicine, such as nursing, pharmacy, publishers, etc. The New York City lists contain 2,435 names, an increase of one hundred names in the year. The editor states that in addition to these, who are accounted "regular," there are 870 who sail under one name or another, and nearly one hundred are known as advertisers. The New York State list has 8,394 names, an increase of about 250, as compared with last year.

The editor earnestly calls the attention of the profession to the growing numbers of people who resort to the public charities. The reports of the dispensaries, for example, show that 442,000 cases were treated at those places, a fact which means either that there is a large increase of pauper sickness or that hosts of persons are treated without charge, who would otherwise employ a physician. There were 6,500 cases treated in the various hospitals.

Regional Anatomy in its Relation to Medicine and Surgery. By George McClellan, M.D. Vol. ii, 4to, pp. 414. Philadelphia: J. P. Lippincott & Co. 1892.

In our notice of the first volume of this recent addition to our already long list of works on anatomy, we expressed our high appreciation of this work, and now that the concluding volume has made its appearance, we can only reaffirm what we then said of the highly conscientious style of the author, the excellence of the illustrations, and the typographical merit of the book as a whole.

It is scarcely too much to say that the present high standing of medicine and surgery as a science is due chiefly to more correct anatomical knowledge, and when we examine the records of the past we find that in every period of the world's history where the study of anatomy languished, medicine and surgery showed little advance and often actual decay, and we sometimes fear that our progressive and pushing age is neglecting anatomy, that foundation of all solid progress, for transcendental medical and surgical therapeutics. It was the teaching of anatomy that made the ancient Greek medical writings and the Alexandrian school immortal, and the impetus given to medical science in the sixteenth century was solely due to the discoveries made in human and comparative anatomy.

But regional anatomy, such as Dr. McClellan sets forth, is the connecting link between the theoretical and practical. It describes the members as they are found, in association. Regional anatomy is thus of much higher value to the practitioner, than the description of separate parts, indeed one must recall with a smile how Alerneon, the first descriptive anatomist, in mentioning what we now know as the Eustachian tube, was led into the belief that goats respired through their ears, and it was given to Aristotle to demonstrate that this tube had no particular connection with the respiratory function. The study of particular parts, therefore, unless supplemented by their collective study, may lead to serious error.

The volume now on our table, devotes eighty-one pages to the region of the abdomen, and the remainder of the four hundred pages in proper proportion to the inguinal region; the region of the pelvis, the region of the perineum; the region of the back; the lumbar region; the gluteal region; the region of the hip; the region of the thigh; the region of the popliteal space; the region of the leg and the region of the ankle and the foot.

The illustrations are excellent color reproductions from original color sketches from actual dissections by the author, and the letter press is large, handsomely printed on heavy paper, and the publishers may congratulate themselves that they have done their part in furnishing a welcome and creditable addition to American medical literature. J. B. H.

NECROLOGY.

Prof. Theodor Meynert of Vienna, has died, and left a notable vacancy in the University faculty of that capital. He was an indefatigable worker in psychiatry, a branch of medicine, which before his day existed only as a name without meaning—"a chaos with no hope of order being restored." This was the expression of Nothnagel, while Zuckerkandl said that the medical world owes it to the dead professor that he opened up a new epoch, since it was Meynert who paved the way to a precise expression of symptoms for localization. His writings had been numerous and varied, but his anatomy of the brain should be sufficient to immortalize his name. Every department in the University suspended the regular routine long enough to pass a tribute, fuller or briefer, to the memory of Meynert, and when Nothnagel addressed his class, all the students arose and remained standing while the professor pronounced his eulogium upon the departed colleague.

American Pediatric Association.—Officers elected for the ensuing year: President, Dr. Blockader of Montreal; First Vice-President, Dr. Keating; Second Vice-President, Dr. Earle of Chicago; Secretary, Dr. Samuel Adams of Washington; Treasurer, Dr. Townsend of Boston; Recorder, Dr. Watson of New Jersey; New Member of Council, Dr. Rotch of Boston. New members elected were: Dr. J. P. Crozer Griffith of Philadelphia, and Dr. T. F. Sherman of Boston.

The Maine Medical Association met in Portland on June 9. The following officers were elected: President, Dr. Alfred Mitchell of Brunswick; Secretary, Dr. William Cammett, of Portland.

Officers of Tennessee State Medical Society.—During the session of this State Society, held in Knoxville, the following officers were elected for the ensuing term: Dr. C. W. Beaumont, of Clarksville, President; Drs. A. D. Sruggs, W. K. Sheddan, of Williamsport, and W. A. D. Coop, of Dyersburg, Vice Presidents respectively for East, Middle and West Tennessee; Dr. D. S. Nelson, of Chattanooga, Secretary, and Dr. Walker, Treasurer.

At the annual meeting of the Washington, D. C., Medical Association, the following officers were elected: N. S. Lincoln, President; C. H. A. Kleinschmidt, First Vice-President; H. L. E. Johnson, Second Vice-President. James Dudley was re-elected Secretary, and Samuel S. Adams, Treasurer.

MISCELLANY.

American Orthopedic Association.—The sixth annual meeting of this Association will be held in Room 39, at the New York Academy of Medicine September 20, 21 and 22, 1892. The program is as follows:

The Association will be called to order daily at 9 a.m. There will be an afternoon session at 2 o'clock.

At noon on Tuesday and Thursday the Association will go into executive session for the transaction of business.

On Tuesday evening, at 8 o'clock, Dr. Lewis A. Sayre will receive the members and guests of the Association at his house, No. 285 Fifth Avenue.

At 8 o'clock on Wednesday evening the annual dinner will be held in the banquet-room of the Academy of Medicine. The charge will be five dollars per plate, and members are requested to notify the Treasurer at the earliest possible day of their intention to participate, and accompany the notification with a check for the number of plates desired, with names of guests.

First Day—Tuesday:

1. The President's Address, Dr. Benj. Lee, Philadelphia.

2. Report of a Case of Spontaneous Dislocation of the Hip Joint, Dr. B. E. McKenzie, Toronto.

3. Adduction following Fracture of the Neck of the Thigh Bone, Dr. H. Hodgen, St. Louis.

4. Osteitis Deformans, with a Report of Two Cases, Dr. Henry Ling Taylor, New York.

5. Lateral Dislocation at the Knee Joint due to Local Disease, or Paralysis, with especial reference to Treatment, Dr. T. Halsted Myers, New York.

6. Plaster of Paris Orthopedics, Dr. A. J. Steele, St. Louis.

7. The Orthopedic Treatment of Infantile Spinal Paralysis, Dr. John Ridlon, Chicago.

8. A Report of Two Years' Operative Work in the Hospital for the Ruptured and Crippled, Dr. V. P. Gibney, New York.

9. Lateral Curvature, Dr. E. H. Bradford, Boston.

10. The Classification of Hip Disease, Dr. R. W. Lovett, Boston.

11. A Study of some of the Problems in the Mechanical Treatment of Hip Joint Disease, Dr. Newton M. Shaffer, New York.

12. Experiments Demonstrating the Etiology of the various Deformities in Hip Joint Disease, Dr. A. M. Phelps, New York.

13. Some Remarks on the Etiology of Club-Foot, Dr. Samuel Ketch, New York.

Discussion to be opened by Dr. J. K. Young, of Philadelphia.

14. At what Age shall the first Treatment of Congenital Club-Foot be Instituted? Dr. H. Augustus Wilson, Philadelphia.

Discussion to be opened by Dr. C. C. Foster, of Cambridge.

Second Day—Wednesday:

The following papers will be discussed together:

15. The Non-Operative Treatment of Congenital Club-Foot, Dr. A. B. Judson, New York.

16. The Non-Operative Treatment of Club-Foot in Young Infants, Dr. R. W. Lovett, Boston.

17. Manual Replacement in the Treatment of Club-Foot, Dr. Ap Morgan Vance, Louisville.

18. The Treatment of Club-Foot by Continuous Leverage, Dr. Henry Ling Taylor, New York.

19. The Place of Traction in the Treatment of Club-Foot, Dr. Newton M. Shaffer, New York.

20. The Use of the Wrench in the Treatment of Club-Foot, Mr. Robert Jones, Liverpool.

Discussion to be opened by Dr. A. M. Phelps, of New York, and Dr. Roswell Park, of Buffalo.

The following papers will be discussed together:

21. The Operative Treatment of Club-Foot, Dr. DeForest Willard, Philadelphia.

22. Analysis of Bone Operations in Club-Foot, especially Enucleation of the Astragalus, Dr. V. P. Gibney, New York.

22. Treatment of Resistant Club-Foot, Dr. E. H. Bradford, Boston.

Discussion to be opened by Drs. L. A. Sayre and J. B. Bryant, of New York.

Third Day—Thursday:

24. An Easy Way to hold the Operated-on Club-Foot in the corrected Position while the Plaster of Paris Splint Sets, Dr. H. M. Sherman, San Francisco.

25. Means for the Prevention of Relapse in the Treatment of Club-Foot, Dr. B. E. McKenzie, Toronto.

26. Necessity for Mechanical Treatment after Operations for Club-Foot, Dr. W. R. Townsend, New York.

27. A Case of Club-Foot with Rare Complications, Dr. A. J. Steele, St. Louis.

28. Paper on Club-Foot; title not announced, Dr T. Halsted Myers, New York.

29. Paper on Pott's Disease; title not announced, Dr. R. H. Sayre, New York.

30. Paper; title not announced, Dr. H. L. Burrell, Boston.

31. Paper; title not announced, Dr. J. C. Schapps, Brooklyn.

President—Benjamin Lee, M.D.

Vice-Presidents—R. H. Sayre, M.D.; H. L. Taylor, M.D.

Corresponding Secretary—Royal Whitman, M.D.

Secretary and Treasurer—John Ridlon, M.D., 34 Washington St., Chicago.

Committee on Membership—E. H. Bradford, M.D.; A. J. Gillette, M.D.; Samuel Ketch, M.D.; DeForest Willard, M.D.; L. E. Weigel, M.D.

Vermont State Medical Society.—Preliminary program of the seventy-ninth annual meeting of the Vermont State Medical Society, held in Montpelier, Oct. 13 and 14.

Papers (partial list).

1. The President's Annual Address, C. S. Caverly, Rutland.

2. Placenta Prævia, D. G. Kemp, Montpelier. Discussion opened by C. C. Perry, West Rutland.

3. An Analysis of Dosimetry, C. W. Strobell, Rutland. Discussion opened by W. H. Vincent, Orwell.

4. Cholera Infantum, A. E. Moody, Isle La Motte. Discussion opened by Geo. Davenport, E. Randolph.

5. Uric Acid and Urea, Analysis and Significance of, Geo. B. Nichols, Barre. Discussion opened by C. W. Peck, Brandon.

6. The Influenza as observed by me in the epidemic of 1891-92, S. T. Brooks, St. Johnsbury. Discussion opened by M. R. Crain, Rutland.

7. Treatment of Minor Injuries to Workmen, C. B. Ross, W. Rutland. Discussion opened by C. E. Chandler, Montpelier.

8. Some of the Medical Delusions of the past and present, Edw. R. Campbell, Bellows Falls. Discussion opened by H. A. Crandall, Burlington.

9. Injuries to the Intestinal Canal, and their various modes of treatment, E. M. Pond, Rutland. Discussion opened by J. N. Jenne, St. Albans.

10. McBurney's operation for radical cure of Hernia, with presentation of a case, Wm. F. Hazelton, Springfield. Discussion opened by H. Janes, Waterbury.

11. Neurasthenia, A. J. Willard, Burlington. Discussion opened by H. R. Wilder, Swanton.

12. Diphtheria—Cause, Prevention and Treatment, F. R. Stoddard, Shelburne. Discussion opened by C. F. Branch, Newport.

13. The Insane Diathesis, J. M. Clarke, Burlington. Discussion opened by D. D. Grout, Waterbury.

14. The use of the Curette in Uterine Surgery, Albert Vander Veer, Albany, N. Y. Discussion opened by L. M. Bingham, Burlington.

15. Paper (Title to be announced) B. J. Andrews, Burlington.

16. Obituary of S. S. Clark, M.D., Geo. Dunsmore, St. Albans.

17. Obituary of Joseph Draper, M.D., H. D. Holton, Brattleboro.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 8, 1892, to July 15, 1892.

Col. Charles Page, Asst. Surgeon-General U. S. A., is granted leave of absence for one month, with permission to apply for an extension of one month.

Major J. V. D. Middleton, Surgeon U. S. A., will take charge of the office, and perform the duties of the Medical Director, Dept. of the East, in addition to his other duties, during the absence on leave of Col. Page, Medical Director.

Major John O. Skinner, Surgeon U. S. A., granted leave of absence for four months on account of sickness, with permission to leave the Dept. of Texas.

SECTION ON PRACTICE OF MEDICINE.

(*Continued from page 105.*)

TRANSMISSION AND BEHAVIOR OF TYPHOID POISON AS OBSERVED IN COUNTRY PRACTICE.

BY LEWIS N. DAVIS, M.D.,
OF FARMLAND, INDIANA.

By a vast majority of the observers who would seem best calculated to know the facts, typhoid fever is now thought to be due to the invasion of the blood by a specific microörganism, known as the germ of Eberth, or the bacillus typhosus. The same observers believe that water is the principal, in fact, almost the only, medium that operates in the transmission of this infectious germ from its focus development, outside of the human body, to the subject of enteric fever. The germs or their spores are said to be eliminated from the typhoid patient, with the alvine discharges in a totally passive state. They increase rapidly in number and soon develop virulence and activity, under the favorable conditions afforded by filth, heat and moisture.

Water is supposed to be a favorable habitat for typhoid germs[1]. These microbes may find ready access to the surface water by a careless disposition of the stools of typhoid patients; thence they reach the wells and other sources of water supply by surface drainage, by active filtration through porous soils and leaks in water mains. Typhoid germs are transferred to the human system by persons drinking the water thus contaminated. If sufficiently susceptible the system will yield to the infectious material and typhoid fever will follow.

Medical history is replete with apparently undeniable proofs of this theory of transmission and behavior of typhoid poison. Such notable instances as the epidemics of Caterham[2] and Redhill, Eng.; Bordeaux[3], France, Wilkesbarre[4] and Plymouth[5], Pa., and that of Cincinnati, Ohio, seem indeed to offer unanswerable evidence in favor of the possibility of water transmission of typhoid poison. Therefore, the theory of water contamination as a cause of typhoid fever has rapidly grown in the favor of the physicians in the last few years.

Today the unanimity of medical thought on this subject may be conveyed by such declarations as that of Prof. Vaughan who says[6], "There are 350,000 to 400,000 cases of typhoid fever in the United States yearly. Medical men believe these are almost wholly due to impure drinking water." Some observers place the number of infections from impure drinking water as high as 98 per cent[7]. Upon this subject I believe the medical profession occupies an extreme, if not an unwarrantable position. The pythogenic theory of Murchison and the contagious theory of Budd are alike rejected.

Clinical observations in the country do not seem to corroborate these widely prevalent views, relative to water transmission of typhoid infection.

If anything can be determined by the behavior of typhoid poison—whatever that may be—as manifested by its influence on members of isolated families, it is: 1. That water is not commonly the medium which conveys the infection to the human system. 2. That the poison is ordinarily conveyed to the system that becomes infected by the atmosphere in the immediate neighborhood of the typhoid patient, or by the atmosphere immediately surrounding the focus of infection, if the focus of infection be outside of the human body. 3. That typhoid fever is practically contagious. 4. That the poison is probably infectious from the time it escapes from the body of the typhoid patient.

The rural section to which my practice has been confined for a period of twenty years is the most elevated portion of the State of Indiana, being about 1,285 feet above sea-level. It comprises an area eight or ten miles square, which consists of a narrow table-land and flat water sheds, lying between the Mississinewa and White rivers. These rivers afford running water the year round, and are only about eight or ten miles from each other at the point in question. The gentle hills and sloping valleys, together with the streams named, provide ample drainage for every district of the country. The soil consists of glacial deposit, and is, as a rule, of a very heavy, non-porous, compact character. It is composed largely of yellow clay, mixed with a liberal supply of humus, and along the streams with sand. Beneath this drift, at a depth of forty to sixty feet is everywhere found a solid bed of lime-stone.

The drinking water is obtained from wells which are usually about twenty feet in depth. The first ten feet traversed in sinking a well are through the heavy yellow clay just spoken of; thence to a strata of sand where an abundance of water is obtained, is through a very dense, sticky blue clay. Both kinds of these clays are almost impervious to water, so that percolation of surface water into the wells might be regarded as practically *nil.* It can only be in the fewest possible instances, from wanton carelessness, that surface water finds entrance directly into a well through slight depressions or furrows in the ground. The wells are usually thoroughly protected against surface water by embankments, and the whole arable country is well drained with a perfect system of tiling.

The farmers are well-to-do, and are usually tidy about their premises. As respects their sanitary surroundings, they are quite abreast with the average of their class, in the best agricultural sections of any country.

But a little more than two generations have passed since the white man first broke the soil. The history of early settlers affords but very few well authenticated cases of typhoid fever. The great scourge of the Hoosier, from the time the first forest trees were felled until the year 1879, was malarial poison. Malaria in its multiferous forms, prevailed from August till December. For the past twelve years, from some unknown cause, malarial fevers have been superseded by typhoid. Typhoid fever now constitutes the prevalent autumnal disease; it prevails in the form of family and neighborhood epidemics and not infrequently extends through the entire winter.

On the 12th day of December, 1886, I was called to see Mrs. B.,[8] aged 46 years.

About a month before this time Mrs. B. had assisted in nursing a neighbor woman who died with typhoid fever. The sick neighbor was situated one mile distant from where Mrs. B. lived. Mrs. B.'s case also proved to be one of typhoid fever. She had two profuse hæmorrhages from the bowels during the continuance of her sickness, and passed many weeks in a very critical condition, but finally recovered.

The Bales family, to which Mrs. B. belongs, consists of the parents and six children. Their residence is a commodious two-story frame building, which has been built three years. The well was dug and the out-buildings constructed at the same time the house was built.

Prior to the attack of Mrs. B., there had been no sickness in the family, save a case of "summer complaint," since the house had been occupied. The fecal discharges of the patient were disinfected with nitric acid or boiling water, carried a distance from the house and buried in the earth. The body and bed linen were changed every alternate day, and strict attention was paid to the cleanliness of the patient, as well as the general surroundings of the sick chamber. However, during the course of Mrs. B.'s case the weather was quite cold, and in order to meet the somewhat fanciful desires of the patient, the house, at times, was kept extremely close and warm. The children occupied an adjoining room to that of their mother during the sickness of the latter. With all the precautionary means, precisely twenty-four days after their mother took sick, five of the children aged from 8 to 18 years began to manifest symptoms of the disease.

The subsequent three weeks gave full development to all the phases of the typical and grave typhoid fever in each of the five children. All recovered.

Thus the epidemic which had been produced by the imported poison, ended with the infection of the five children.

There were but very few, and only transient visitors in the Bales house during the prevalence of their family epidemic. The nursing was in charge of Mr. Bales and his eldest daughter—two of the most rugged members of the family—both of whom escaped the disease entirely.

The following is a brief history of an interesting neighborhood epidemic in which the first case made its appearance in a family by the name of Adams:

The Adams family consists of six persons: Mrs. Adams, aged 73 years, her son and his wife, and three small grandchildren.

The family has lived on the place now occupied a part of three generations, covering a period of fifty-two years.

The water is supplied by a well which has been in constant use by the family for forty years.

One case of typhoid fever is said to have occurred on the Adams farm within the fifty-two years of the family occupancy, the date of this case being in September, 1847—almost forty-five years ago.

On the 14th day of October, 1891, the senior Mrs. Adams visited a married daughter, seven miles distant. There were five cases of typhoid fever, in various stages of progress, in the family visited.

Mrs. Adams returned to her home in a short time, and after several days of complaining, she took her bed on the 6th of the following November. She soon became stupid, semi-conscious and comparatively helpless.

As she was visited only a few times by a physician, in the early part of her sickness, before the development of the more characteristic symptoms, the diagnosis of the case was left in some doubt. Suffice it to say, that Mrs. A.'s case was attended by many symptoms of typhoid fever, including a very profuse and troublesome diarrhœa. Owing to her helpless condition, the nurses placed pads under the hips of the patient, and the bowels were evacuated *in situ*.

As the old lady was quite a care in her last sickness, a goodly number of neighbors and relatives lent a helping hand in nursing her.

Among those actively engaged in attending the sick woman were five couples—men and women—belonging to as many distinct families, but including Mr. J. A. and wife of the Adams family. The remaining four couples, or families, live respectively one-quarter, one-half, three-quarters and four miles distant from the Adams house.

All of these ten persons[9] who participated in nursing Mrs. A. were of about middle age, and enjoyed an average degree of health.

The interior of the Adams residence is very uninviting. It consists of one large, and two or three smaller rooms, all of which are dark and poorly ventilated. The sides of the rooms are covered with old wall-paper, which is hanging loose in many places.

The nurses, callers and the sick, promiscuously occupy the larger room together much of the time, heat being generated by a huge wood-stove, which is in close proximity to the sick-bed.

Mrs. Adams was buried on the twenty-third day after taking her bed, at which time there were but half of the nurses able to attend the funeral; and within thirty-three days after Mrs. A. senior took sick, all of the ten nurses had typhoid fever.

With but two or three exceptions, the cases presented the roseolous rash, had epistaxis, and all of the leading features of grave typhoid. They all recovered but Mr J. A. of the Adams family, who died on the thirty-fifth day of his illness, with hæmorrhage from the bowels.

It is supposed that each of the three grandchildren in the Adams family had a slight attack of typhoid fever, as they were very much indisposed during the sickness of their parents.

In addition to the nurses already mentioned, there were a few transient callers at the Adams house during the course of the first case. Among the number was Miss M., aged 18 years, who was induced to remain at Mrs. A.'s wake on the night of November 28.

Twenty days later Miss M. took typhoid fever.[10] She had the roseolous rash, and in all respects a typical attack of typhoid, from which she recovered in about thirty days.

She ate nothing during the night when at the wake, and partook of no liquids save a few swallows of water just before her departure in the morning.

This, the fourteenth case, concludes the number of infections that occurred at the Adams house during the sickness and before the burial of Mrs. Adams, by whom the poison was undoubtedly transported thither from a distance of seven miles.

There were three other infections in the Adams house after the death of the first case, as follows: Mr. and Mrs. Mills went to nurse J. A. and wife, on the Adams farm, in the early part of December. Both took typhoid fever twenty-one days thereafter; both recovered.

Mr. W. R., aged 24 years, was then hired to go to the Adams house and wait upon J. A. and family. He began duty on the 28th of December, 1891. Twenty-one days after he entered the infected locality the first symptoms made their appearance, and soon he was confined to his bed with a very severe case of enteric fever. He recovered in about six weeks.

When taken sick, Mr. R. was lodged in the farm residence of Mr. Hammers, about one mile distant from the Adams place. Good nursing was secured throughout the course of the case.

---

[8] See Jour. Am. Med. Ass'n, vol. x, p. 483.

[9] They occasionally took meals and drank water at the Adams house.

[10] Miss M. lives one mile from the Adams house.

The patient's stools, which were very frequent, were carefully disinfected with three or four times their bulk of boiling water, carried 200 yards from the house and buried in the ground.[11]

The body of the patient was thoroughly sponged with dilute alcohol two or three times daily, and the body and bed-linen kept scrupulously clean. The desired ventilation could not be always attained in the sick-chamber, however, on account of the prevailing cold weather, which frequently necessitated closing both doors and windows.

The Hammers family consists of Mr. H. and wife, aged 75 and 72 years respectively, their daughter and three grandchildren.

Mr. H. was the first settler on his place, and has occupied it since 1837. In all respects the home is a model one for taste and cleanliness, from the interior of the residence to the farthest limits of the farm. Prior to the present outbreak, there has never been a death or any bad sickness on the Hammers farm.

The well is situated on high open ground, several feet from any building, is 20 feet deep, and has supplied the family with water for twenty-two years.

In from twenty to thirty days after the reception of Mr. R. into the Hammers residence, the three grandchildren were attacked with typhoid fever, and on the 28th day of March, or two months after the entrance of the first case into the family, Mrs. H. took the fever, and died twenty-one days later.

The origin, course and decline of many similar limited country epidemics might be detailed, but without presenting any especial features not contained in those already given. I have intentionally refrained from reporting any local outbreak of typhoid fever in which it was not possible to trace the origin of the first case to some distinctly infected source—my purpose being to assist with this means, in making it clear that the infection did not exist on the premises where the epidemic occurred, prior to the development of the case, which is here regarded as initiating and spreading the epidemic.

It is beyond the limits of the subject to combat the theory of water transmission of typhoid fever, and far beyond the limits of my ability to do so with much hope of success.

But if able to exhibit any inconsistencies in the theory of water contamination as the *chief* cause operating in the spread of typhoid fever, even in a single locality, much will have been accomplished in favor of the theory of atmospheric transmission of the poison.

The inconsistency of the view which holds that water is the chief carrier of the *materies morbi* of typhoid fever becomes apparent when applied to the behavior of the poison, after it has been transported from an infected to a previously healthy locality, as in the case of Mrs. B., who became infected on her neighbor's premises. She carried the infecting principle a distance of one mile, into her own home, where there was not the slightest reason to believe that it had ever existed before. Twenty-four days after the poison had gained a foothold in this virgin soil at the Bales home, it was capable of striking down the five children.

Could it be possible that the infectious material that might have been contained in the discharges from Mrs. B.'s bowels, had found its way into the water of the recently dug well, thence into the system of the five children, within the lapse of twenty-four days?

Such a view certainly cannot be made to appear tenable, when it is remembered that the discharges in Mrs. B.'s case were very carefully dealt with.

The same incongruity of thought will occur, if the theory of water pollution be offered as an explanation of the spread of typhoid fever in the Adams epidemic.

Here the typhoid material was undoubtedly conveyed by the first subject from a notoriously affected locality, a distance of seven miles, to a farm that had not known a case of typhoid fever for forty-five years. Yet, within twenty-two days after the transported poison began to manifest itself in this newly infected locality, it had five more victims, a little later ten, fourteen, then seventeen.

Can it be said that this well from which the family had been supplied with water for forty years without any untoward developments, had become charged with typhoid poison in the space of twenty-two days? Impossible! Did Miss M., who staid at the Adams wake on the night of November 28, swallow the typhoid material in a few sips of water? I do not believe so.

Again, in the Hammers family, where the poison was transported by Mr. R. from the Adams focus of infection, one mile distant, to a farm that had been noted for the health of its inhabitants for fifty-five years, the premises suddenly becomes a hot-bed for typhoid fever. Could the water supply from which the family had been furnished for twenty-two years be responsible? Was the water answerable for the four cases of typhoid fever that followed in from one to two months?

It is not alone the short time required for the transported poison to assume activity, in a previously healthy locality, that renders the theory of water contamination an improbable cause in the spread of typhoid fever. It is also improbable in the epidemics here cited, as well as all other epidemics of typhoid in this locality, owing to the character of the soil, as previously set forth.

Our wells certainly contain little else than unmixed "ground water," therefore the water must have been subjected to prolonged filtration through stratas of sand and gravel before reaching the wells, by which process, according to high authorities,[12] it is freed from any pathogenic microbes it might have contained.

Is it not possible that a relationship between malarial and typhoid fevers may yet be found in the fact that the latter now prevails in many localities at the expense of the former?

Typhoid fever is undoubtedly contagious by mediate contact; and atmospheric contamination offers the only plausible explanation of the spread of the disease in each of the epidemics just given.

The contagium, which certainly escapes with the exhalations from the body of the patient, as well as with the dejections from the bowels, must be active at the moment it is liberated from the typhoid subject, because there is no difference in the length of the stage of incubation in the first and second set of cases infected by a transported poison.

The infected atmosphere may reach every apartment in an ordinary farm dwelling which contains a typhoid patient, when the conditions are favorable

The conditions are favorable in the winter time, when it is impossible to secure perfect ventilation in country houses, on account of cold weather. The conditions are still more favorable when, conjoined with improper ventilation, there is little attention paid to the cleanliness of the patient and his surroundings.

---

[11] The stools of the patients on the Adams place were neither disinfected nor buried, but carried quite a distance, down a slope, from the well and house.

[12] Bertschringer, Gazette Médicale de Nantes, July, 1890.

The country population experiences but few epidemics of typhoid fever in the early autumn, when the doors and windows can be thrown open, and when the application of water can be advocated with the perfect approval of both the patient and the nurse. Like the most of contagious diseases, the infecting material of typhoid may unquestionably be inhaled with the atmosphere which disseminates it.[13] Such accords with our experience in country practice; such are the views of our patrons, and with each passing year we find it more difficult to secure nurses who are willing to engage in the care of typhoid patients.

Discussion.

Dr. Chapin reported that in 1864 he had seen several cases similar to those reported in the paper.

Dr. J. H. Musser, of Philadelphia, thought that before any conclusion can be drawn, the relations of the first case, so far as the infection of drinking-water is concerned, should be worked out. He regretted that, in connection with the report of the Adams family, no record had been given of the disposition of the stools. In this connection, he said, the epidemic of Plymouth, Pa., well known to all, was of interest. It was there shown that the cases arose from one case of typhoid living at the head of the stream which supplied drinking-water to the communities afterward afflicted.

Dr. Davis, in reply, stated that the stools of the Adams family were not disinfected, but were thrown out upon the ground at a distance. He had failed to mention this fact because he did not think that the poison could reach the well in the twenty-four days which preceded the outbreak of the second case.

A paper was then read entitled

NON-VALVULAR HEART MURMURS.

BY N. S. DAVIS, Jr., A.M., M.D.,

PROFESSOR OF PRINCIPLES AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE, CHICAGO MEDICAL COLLEGE.

By non-valvular heart murmurs I mean heart murmurs that are produced without structural change in valves. Such murmurs are common. They often cannot be distinguished from those that are produced by valvular deformities. The physical signs which accompany valvular lesions enable the diagnostician to locate the morbid process and to determine the character of interference with the circulation which it produces, but does not make it possible to decide on the pathological character of the lesion.

I call attention to the following cases to emphasize the fact that not unfrequently the murmur of a non-valvular lesion is the same in character and location as a valvular one, and that it may be accompanied by the same changes in the size and shape of the heart and other organs.

A man about 45 years old, entered Mercy Hospital suffering with distressing dyspnœa. He coughed little. He was moderately œdematous about his feet. He complained of no pain. His heart was enlarged to the left moderately. Its area of dulness extended about two-thirds of an inch to the left of the nipple line and to the centre of the sternum. The apex beat was strong and easily discernible, though the chest wall was thick. It was moderately diffused and not quite regular. There was throbbing just beneath the sternum of moderate force. No thrills could be felt over the heart. The precordia was not prominent. A systolic murmur was audible all over the heart, but was loudest and clearest at the apex and lowest and most obscure over the aorta. The patient's liver was about one inch broader than was normal. He had no abnormal temperature while he was at the hospital. His urine was normal in amount, slightly cloudy, of a dull straw color and a specific gravity of 1028. It contained considerable albumen. When the latter was coagulated by heat and permitted to settle thoroughly it constituted about one-sixth of the bulk of the urine tested. Granular casts, a few granular epithelial cells and some amorphous granular matter was found in the urine's sediment.

The patient began to be dyspnœic about a week before he entered the hospital. His feet became œdematous at the same time. He had been slightly short-breathed for months. A year prior to this last illness he suffered with acute articular rheumatism. He had been a laborer and was accustomed to use alcoholics freely.

The urine indicated a chronic nephritis. The enlargement of the liver, evident engorgement of the lungs, and dilatation of both ventricles with probably (as the force of the apex beat indicated) some hypertrophy, and a cardiac murmur most intense at the apex, pointed to a mitral valve lesion. The former rheumatism afforded a cause for endocarditis. The shortness of breath which the patient experienced during the year prior to his last illness was supposed to be of cardiac origin. It was thought that the nephritis might have grown out of a passive hyperæmia of the kidneys.

A few days after he entered the hospital a pain of considerable intensity and persistence suddenly developed in his right forearm. The arm also rapidly became œdematous. There was tenderness about the painful point. This new lesion was evidently due to an embolus. In a week the arm was normal in size and all pain had disappeared. He gradually improved so that he could lie down to sleep. The œdema of his feet lessened. Again he was taken worse and became rapidly very dyspnœic. His breathing grew shorter and more labored as his lungs filled with an œdematous exudate until it ceased.

On post-morten examination his kidneys were found enlarged and presenting the usual aspect of parenchymatous nephritis; the liver was slightly enlarged from congestion. His lungs were œdematous and a small amount of serum was found in the left pleural cavity; the heart was enlarged and soft. The walls of the ventricles were normal in thickness. No lesion or deformity of the valves was discoverable,but a fibrinous clot whose largest mass was a half inch in thickness, was intimately intertwined amongst the chordæ tendinæ of the mitral valve. This was evidently not a new clot for it was firmly adherent to the heart's wall at several points. It was tough and firm. The mitral orifice was not abnormally large. The murmur must have been due to the interference which this clot presented to the closing of the valves and a bit of it formed the embolus which caused his arm to swell. The renal disease was plainly the primary one. The blood-state which nephritis produced predisposed to the clotting of the blood in the dilated heart. The interference with the circulation which the clot caused was precisely that which a contraction of the mitral valves by scar-tissue or other inflammatory change might produce, therefore the physical signs which resulted were the same.

Another case of cardiac murmur due to a heart thrombus, I observed develop in a similar case of nephritis. A young man of thirty-five had nephritis for at least two months before a physician was consulted. When seen by me he was quite œdematous,suffered much from nausea and occasionally from dyspnœa. A severe headache tormented him at night. He had supposed the œdema of his feet was a rheumatic swelling of them. He made only about one half the normal quantity of urine. It was turbid and contained an abundant sediment. In the latter granular and epithelial casts were numerous. There was much amorphous granular matter, a few granular epithelial cells and oil droplets. The urine was strongly albuminous. During the two weeks that followed, the patient grew gradually weaker with, from day to day, varying degrees of comfort and discomfort. He then kept his bed continuously although the œdema had nearly disappeared and the nausea and vomiting had wholly. His urine had increased so that it was little less than normal. While for the most part free from pain or suffering, he felt his weakness greatly. Often at night he felt anxious for air and demanded that the windows be opened,thoughhis breathing was not increased in frequency and there was no evidence of obstruction to the bronchial tubes. His heart was easily excited from the beginning of his illness. Usually his pulse varied from 80 to 90 beats per minute, but slight exertion made it quicker. It was rather small and soft. His skin had the sallow anæmic hue which characterizes chronic parenchymatous nephritis.

About two weeks before his death I found at my morning visit that there was audible over the heart a double systolic beat. The two systolic sounds were perfectly distinct and exactly alike in character. His pulse was then 130 per minute. He felt extremely weak and momentarily faint. The systolic reduplication persisted during the half hour that I sat by him. I returned to him about three hours later and then found the double systole gone but a plain murmur audible along the lower right border of the sternum and over the lower end of the bone. It was loudest and clearest in the second intercostal space just to the left of the sternum. It was less plainly audible over the aorta than at the lower end of the sternum and was inaudible at the apex. The murmur was soft, low and systolic in time. Over the pulmonary artery the second sound was wanting. The heart had not changed in size or shape. For a week its area of dulness had extended from the left nipple a trifle to the right of the sternum. The apex beat was scarcely discernible and could not be plainly felt. There was no substernal throbbing. The cardiac murmur which had thus developed persisted to the patient's death. It seemed to me plainly a case of cardiac thrombosis in the right ventricle and interference with the action of the tricuspid valves upon that side.

---

[13] Experiments of Sicard. See Jour. Am. Med. Association, Editorial, Vol. xviii, p. 467.

The patient died 16 days after the cardiac murmur developed. An autopsy displayed kidneys with the characteristic appearances of the patient's disease. The heart was moderately enlarged, a little soft and of normal color. The interior of the left ventricle and auricle was normal. In the right ventricle, adherent to its walls, intertwined with the chordæ tendinæ and muscular papillæ was a large clot of a dull white color and very firm consistence. In the ventricle it was spread out and much divided, but was concentrated into a large, ropy mass a third of an inch in diameter and three inches long, which extended into the pulmonary artery.

These cases are especially interesting as illustrations of the length of time clots may exist in the heart, though not perfectly organized, and the possibility of cardiac murmurs being produced by them. The thrombi formed in these two cases resembled those that are commonly produced just before death when, as often happens, the heart beats with rapidity and feebleness but they were firmer and their interiors were dryer. When they were removed from the heart the endothelium was torn off in small spots where the fibrin had become attached.

It would be difficult to explain the development of a heart murmur in the second case except by supposing a cardiac thrombus existed such as was found after death. There also existed a blood state which disposes to thrombosis and when the murmur developed the heart was beating with great rapidity and feebleness. In a word the most favorable conditions existed for the formation of a thrombus.

A third case of cardiac murmur with associated physical signs which simulated mitral insufficiency, was first seen at my office:

A woman about 35, with a small family, came to me with feet much swollen, considerable shortness of breath on exertion, frequent coughing, irregular and rapid beating of the heart. Her face and chest were rather thin. She was sallow. I found her pulse medium in size, soft, quick and irregular. She had little appetite. She did not complain of indigestion. Her bowels were constipated. She thought her urine was a little less than normal in amount. A sample brought some days later contained no albumen and appeared normal. She menstruated regularly. Her cough was bothersome because of its frequency. She expectorated, not copiously, a frothy sputa. A physical examination of the chest exhibited the usual evidences of a diffuse bronchitis of moderate severity. The precordia was a little more prominent than natural. The heart's apex beat could be faintly felt and scarcely seen. No substernal throbbing could be felt except upon deep pressure in the epigastric region where there was considerable tenderness. The area of cardiac dulness extended to the left nipple and for two inches directly below it; and to the right border of the sternum. No abnormal fremitus could be felt over the heart. A soft systolic murmur was plainly audible at the apex and to the left of it, and less plainly near the lower end of the sternum. At the base the first sound was normal but over the pulmonary artery the second was accentuated. The liver was a little depressed and slightly broader than natural. The case seemed plainly one of mitral insufficiency with slight dilatation of both ventricles, considerable cardiac weakness; bronchitis and moderate emphysema; moderate engorgement of the liver and general œdema. Relief was readily obtained by cardiac tonics. In two weeks the œdema was altogether gone; her cough almost gone; her breathing was easy except when quite rapid movements were made. Her appetite returned. In every way she felt greatly improved. A physical examination revealed very little change in the signs of cardiac disease except that the heart beat with regularity and greater force, the apex was more plainly visible though its impulse was feeble. I lost sight of the patient after this for 4 months. I was then asked to visit her. She had been in the country and for the first 3 months did well. During the last month her old troubles—cough, dyspnœa, œdema, inability to eat and great debility returned. She was confined to her bed and compelled to maintain a semi-recumbent position. She was able to sleep very little because of her cough and dyspnœa. Her abdomen was distended with ascites. Her urine was scant and contained a small amount of albumen but no sediment. Her heart was very rapid and irregular. Otherwise the physical signs of cardiac disease were the same as when I saw her first. The pulse was small and soft. She was so imperfectly cared for at home that I urged her to enter Mercy Hospital. She lived only four days longer. An autopsy demonstrated firm adhesions between the pericardial surfaces except posteriorly. In front, underlying the lower part of the sternum and extending to the left of it to the apex, was a hard, immobile plaque of partly calcified fibrous tissue, about 2 inches broad and 4 inches long. It covered most of the anterior surface of the heart. It was cut with difficulty and at points was completely calcified. The ventricular walls were moderately hypertrophied. The valves were quite normal and the valvular orifices were not distended.

She never recalled any attacks of pericardial pain or tenderness, but had acute articular rheumatism two years before she was first seen by me. After that she suffered from bronchitis frequently and was constantly dyspnœic when she exerted herself much.

This case again illustrates the fact that the usual combination of signs of a valvular lesion may coexist though the cardiac valves are without flaw.

Pericardial adhesions can rarely be diagnosed and certainly not when a fibrous or calcified pericardium makes systolic retraction of the sternum and intercostal spaces impossible. Such adhesions are occasional causes of systolic murmurs. The mechanism of these murmurs cannot be certainly explained. They are, however, probably due to irregular contractions of the muscle fibres composing the heart's wall, so that unusual currents or eddies are produced in the blood within the heart.

Anæmic murmurs are so common and usually so easily recognizable, that they scarcely need comment. The signs to be relied upon for their diagnosis as stated by the best authorities are the following: Anæmic and functional murmurs are usually soft, blowing and systolic. When most characteristic they are clearest and loudest about one or one and a half inches to the left of the sternum in the second interspace. Sometimes they are most audible a little lower or even at the apex. When at the apex they are usually heard in a very circumscribed space. They are never loudest over the aorta. Hypertrophy of the heart is not associated with anæmic murmurs though dilatation often is. Murmurs in the veins of the neck are frequently present in anæmic states.

Murmurs due to valvular disease may also be soft and blowing. Though functional murmurs are almost uniformly systolic, they may rarely be diastolic. Murmurs heard at the base of the heart and well to the left of the sternum are uniformly anæmic, but occasionally may be confounded with pulmonary murmurs and the rare mitral murmurs which are heard plainest over the auricle. These latter when characteristically located are close to the sternum. Functional murmurs, I believe, are often loudest at the apex. They are, however, rarely much diffused or propagated to the left into the axillary space, but as in the case of fibroid pericarditis, which I have just described, they may be diffused and transmitted as valvular ones commonly are. An intense anæmia is not much more liable to be accompanied by a cardiac murmur than one of moderate severity.

Soft systolic murmurs occasionally develop as convalescence is being established in rheumatism when the blood has become moderately thin. In two such cases I have heard the murmur only in a small space at the apex. The heart in each instance was slightly dilated, beating rapidly and with feeble force. Under tonic treatment in the course of two or three weeks, the hearts regained their vigor and the murmurs disappeared. Such murmurs are undoubtedly functional and do not signify endocarditis. An endocarditis which can produce a murmur usually develops before convalescence begins and very rarely disappears entirely. Accidental or functional murmurs are quite as likely to develop after rheumatism as after other fevers and prostrating diseases.

It is true that for the diagnosis of a heart disease the *tout ensemble* of cardiac physical signs is of the greatest importance, the mode of their development, the condition of the patient before and at the time of examination, the existence of a former illness such as rheumatism or chorea, the progress and complication of the affection, in a word the medical history of a case is of equal importance. A diagnosis often cannot with safety be based upon physical signs only.

65 Randolph Street, Chicago.

Discussion.

Dr. Newcomb, of New York, referring to his own experience as examiner for an industrial branch of one of our large insurance companies, stated that he frequently made examinations of individuals who had just come in from work, frequently too after a long walk, and that he had found that murmurs are sometimes distinguishable under such circumstances which are not at all audible in repose. In certain cases of long-standing debility there is a regurgitation through a valve which is not due to disease, but due simply to the relaxation of the orifice. Murmurs of overaction are explained as due to the fact that the action of the ventricle becomes so powerful that the mitral valve is not able to close the orifice completely, and blood is forced back into the auricle.

Dr. Kennedy, of Michigan, remarked that in examinations of boys for the Navy, murmurs have been found which could not be accounted for except as a result of cigarette smoking. Murmurs were also found in the recumbent posture which could not be found in the erect posture.

Dr. Davis explained that the time at his command had not been sufficient to go into the consideration of the cause of this condition. All the explanations that have been given are purely theoretical. We have no experimental proofs as to the causation of these murmurs. The formation of a fibrinous clot as a cause of the murmur is not essential, but probably does occur frequently. He felt confident that this was the cause of the murmur in his second case, from the character of the murmur and from the character of the clot.

The title of the next paper was:

THE IMPORTANCE OF POSITION IN EXAMINATION OF DISEASES OF THE HEART.

BY O. B. CAMPBELL, M.D.,

OF OVID, MICH.

The heart (the only organ in the body which is never at rest) with its investing membranes, the serous and fibrous pericardium, is situated in the median line of the thorax, and occupies the entire space between the two lungs and pleuræ. This pericardial sac includes the heart, the origin of the large blood vessels, and possesses very complete fixation. Next to the pelvis Paul claims the pericardial sac to be the least movable region in the human body. Its apex is fixed to the skeleton by three ligaments, one coalescing with the inter vertebral ligament of the third cervical vertebra; another uniting with the middle aponeurosis of the neck is inserted into the hyoid bone, the other passes anteriorly to the sternum.

The base of the pericardium is fixed to the centre of the diaphragm and through the medium of this muscle is united posteriorly to the spinal column, and anteriorly to the ensiform appendix.

Now, the heart, which may be compared to a hollow muscle acting like a great force pump to propel the blood through all parts of the body, is kept in place by the great vessels which spring from its base, and by the attachments of its investing sac, the pericardium, which has been shown by before stated anatomical facts to be fixed solidly to the skeleton, and therefore changes its position but little, during the respiratory movements of the diaphragm, hence the apex beat in a normal heart is but slightly raised or lowered during inspiration or expiration, and whether the patient is examined either lying down or standing; but on the other hand quite marked displacements may be observed in abnormal cases where hypertrophy has increased the weight of the organ, and the resistance of the ligaments has been gradually overcome.

Altered posture of the body always displaces the normal heart transversely which sinks from three to six centimeters when lying on the left side, and from one to three centimeters during right decubicus. Position also illustrates the effects of gravity on the heart in the greater force and more extended apex beat, when the chest is bent forward, a procedure that should always be practiced when this beat is obscure.

In position the axis of the heart is directed from above downwards and to the left, two-thirds of its bulk passing to the left, and one-third to the right of the median line of the sternum. Its upper border corresponding to a line drawn across the sternum on a level with the upper border of the third costal cartilages, its apex lies immediately behind the sixth left costal cartilage inside the mammillary line. The lungs passing downward from their apices meet each other behind the sternum at the level of the second rib and are separated only by the mediastinal fold of the pleura until they the reach level of the fourth rib where they again diverge. Thus it will be seen that both auricles and part of the ventricles are completely covered by lung tissue, which is a very bad conductor of heart sounds, but after the divergence of the lungs at the level of the fourth rib we have about one-half of the right ventricle and the apex of the left, between which and the chest wall no lung tissue intervenes, yet the extent of heart surface not covered by lung tissue is subject to constant variation; during deep inspiration the edges of the lungs may converge so as to cover the entire surface of the heart, and on the other hand during forcible expiration the margins of the lungs recede to such an extent that the larger part of the heart's surface comes close to the chest wall.

The extent of the movement of the thorax in normal respiration is also controlled to some extent by the position of the body, and is one-half centimeter less in lying down than in standing, also in turning from the back to the side in the recumbent position the lung which is uppermost descends from two to three centimeters.

From what has been said concerning the anatomical relations of the heart and lungs it is evident that in the normal condition of the thoracic viscera, the heart is but little displaced vertically by a change in the position of the body, but that its transverse position is readily affected by such change, also that the principle obstacle in the conduction of the sounds of the heart is the presence of lung tissue between the organ and the walls of the chest, which shows the great necessity of not only examining a patient during tranquil respiration, but also during forced expiration.

I now wish to speak of one position in auscultation of the heart which I regard as of great importance and in which I am compelled to disagree with some of our standard authorities. Paul Guttmann says all murmurs are louder when the patient stands or sits than when he is recumbent. I now wish to say that nearly all murmurs are louder when the patient is recumbent than when he is standing or sitting. I am willing to admit that in somewhat rare instances murmurs can be heard more distinctly in the erect than in the recumbent position, but in a large majority of all cases where murmurs are detected in the upright position they will be greatly increased by placing the patient in dorsal decubitus. According to my own observations this rule holds good in 78 per cent. of all cases examined.

I will here give statistics of one hundred consecutive examinations in which I have kept a record to determine this point (and so far as I am aware they are the only statistics which have been collected bearing on this matter) which are as follows:

Total number in which murmurs increased during dorsal decubitus, 78. Murmurs not effected by changing position of body, 12. Murmurs not perceptible in standing, but developed on lying down, 4. Murmurs more developed in upright than in recumbent position, 6. These examinations were all made upon the soldier population of the State of Michigan, and each applicant was carefully examined by my two colleagues, and the accuracy of these statistics fully concurred in.

This was followed by a paper on

NUTRITION.

BY M. J. CROUCH, M.D.,
OF UNION, KY.

I do not propose to present to you more than a suggestion of the merits of nutrition, and its relation to pathology. My studies along this line have forced me to conclusions which seem of vital importance to the science of medicine. It is true, our conclusions are more or less colored by the environments of the place from which we view the subject—so let us view the subject from analogous laws of nature.

From the true scientific standpoint, in the organisms lie the principles of life, in the environments the conditions of life.

The cart has been before the horse long enough—let us reverse the awkward position, and place them in a more practicable way. Instead of teaching that an *abnormal nutrition* is the *result* of "*disease*," let us teach that "*disease*" is the result of abnormal nutrition. Then, and not till then, will we make progress toward the goal of medical science.

The most important part of physiology is *nutrition.* The most important part of pathology is *nutrition.* Disease is not an entity, but the result of an abnormal or vicious nutrition. It is a process, differing from the normal processes only in *form* and *course.* All normal growths must be nourished, or they degenerate and die. So all morbid growths must be nourished, or they undergo like changes. What is the difference between the two conditions? Only a difference of nutrition. In the former it is according to natural laws, in the latter in violation of those same laws—it is vile.

There are natural laws reaching across the length and breadth of the whole organic world. Even the inorganic world is not without laws. Thus, from the lowest to the highest, *all* are subject to the powers that be.

Chaos does not exist anywhere in the known world; not since the hand of God moulded it into the things that be. Seeing all things are subject to natural laws, it is not reasonable to suppose that the most perfect creatures of God's handiwork, even the crowning piece—man, should be a monstrosity in the universe. Yes, man was created under, and lives and dies under natural laws, as well as spiritual laws, *which spiritual* laws are but a reaching upward of the laws of nature.

Progress is expected, and nutrition emphasized, in every part or parts, portion or portions of the known organic world. It is the same cry that has come rolling down the ages, and has found an echo wherever organic matter lived, from time immemorial: "Give us bread or we die." So demand all living organic bodies, and man is no exception. Then, if an end is so important, the means unto that end must be of vital importance.

Life is the desideratum of all living creatures, and nutrition is an absolute necessity—*the only means to that end.* Then nutrition must be the most important process in life.

Is it "fever" you would inquire about? Is there not a normal heat production in all living organic bodies? Find its source, form and course, and you will have no trouble with the abnormal condition, for every abnormal—diseased—condition has its prototype in the normal, physiological. It could not be otherwise according to the laws of nature. When the nutrition of the body is normal, the heat produced and functions performed by that body are normal.

When the nutrition is abnormal, the heat produced and functions performed by that body are abnormal, and as varied in results and as far-reaching as pathology. Thus inflammations, hyperplasias, hypertrophy and different degenerations may be due to the same form of nutritive disturbance, the different results due to the different *course* pursued. The cause is the same, the results varying as the form and course vary. These varieties may become less numerous, as we become more familiar with the cause. You wish to know the nature of this cause? I told you that nutrition was at fault—*first*, last, and all the time. The causes of this faulty nutrition are predisposing and exciting. The predisposing causes would embrace all such as heredity and environment. Exciting causes would embrace all such as were irritating to the organism. Here the field broadens, and the eyes wander over unlimited space, bringing into view many strange things, difficult to see and to understand. It is ever so in a new country to the first explorers. I only hope to point to the way, go as far as I *can*, and trust others better equipped, and time, will open up the way and reap the harvest. So, in concluding these suggestive thoughts, I recapitulate the pertinent point, that normal nutrition is to physiology what abnormal nutrition is to pathology.

The chairman then announced the following Executive Committee for the Section: Dr. H. A. Hare, Philadelphia; Dr. I. E. Atkinson, Baltimore; Dr. N. S. Davis, Jr., Chicago.

THIRD DAY—JUNE 9—MORNING SESSION.

A paper was read entitled

THE CARDIAC INDICATIONS AND CONTRA-INDICATIONS IN THE TREATMENT OF PNEUMONIA.

BY J. M. ANDERS, M.D., PhD.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE AND CLINICAL MEDICINE, MEDICO-CHIRURGICAL COLLEGE, PHILA.

It is a well known fact that in acute lobar pneumonia failure of heart power is the immediate cause of death, as a rule.

In the first place there are three leading factors which enter into the causation of cardiac-insufficiency in this disease, which factors may operate singly or in combination. They may be conveniently considered under as many different heads, to-wit:

First. The heart failure may be due to the toxic effects of the ptomaines present in the blood, on the heart muscle and ganglia.

Secondly. It may be due in part at least to the obstruction offered to the pulmonary circulation by the inflammatory exudate in the air vessicles.

Thirdly. The formation of cardiac thrombi may lead to right ventricular dilatation and exhaustion of heart power.

Pneumonia belongs to the acute infectious diseases, hence it is intelligible that on account of the overwhelming of the system by the ptomaines produced by the pneumococcus, the heart may become exhausted. It is not an uncommon event in the experience of the busy practitioner to meet with instances of this malignant and fatal type of the affection. These cases can as a rule, be recognized during the progress of their brief course. Auscultation of the heart reveals a feeble, short, first sound, associated usually with a feeble aortic and pulmonic second sound. The pulmonary artery second sound is sometimes accentuated when these cases reach the stage of complete consolidation, though most generally for a brief period only. But though the heart power fails under these circumstances there are few special indications presented by the organ for treatment.

Alcohol in *moderate* doses is of the first importance since it aids the digestion, imparts vigor to the heart muscle, stimulates respiration and the nerve centers. We should supplement the action of the alcohol by the administration, of strychnia which stimulates, more particularly, the cardiac nerve ganglia, the vasomotor and the respiratory centers. Digitalis is to be employed cautiously, indeed, is only useful when the pulse becomes very frequent as well as irregular or intermittent. Under these circumstances digitalis, by lengthening the period of diastole, facilitates the nutrition of the cardiac muscle.

In this connection the investigations of Drs. G. and F. Klemperer, carried out to ascertain among other things, whether pneumonia can be cured by the blood serum of immune animals, or those that have recovered from the disease, are of considerable interest and importance.

Their experiments "confined to rabbits show that the inoculation of any nutrient medium, in which the pneumococcus has been cultivated will protect an animal against pneumonic septicæmia. Again, serum from animals enjoying immunity cured pneumonic septicæmia, especially when introduced into the circulation, and this in 24 hours, as a rule. It was found that when the pneumococcus enters the body of an animal it generates a poison 'pneumotoxine' which can be isolated: this sets up a febrile condition, lasting several days, by which time another substance 'anti-pneumotoxine' is formed, and through its influence cures pneumonic septicæmia."

The drugs employed, in the most prevalent methods of combating the local engorgement of the lung in the first stage of pneumonia, for their influence upon high temperature to some extent, as well as upon the heart, are veratrum viride, aconite, and antimony. To the depressing effect on the heart of the pneumonic poison, the majority of physicians are still in the habit of adding the depressing influence of cardiac sedatives. Now whilst I am willing and ready to concede to the facts, that veratrum viride and aconite act as vaso-motor depressants, quiet the heart and relax the blood-vessel walls, I affirm without hesitation that they do so at the expense of cardiac power,—a thing to be scrupulously avoided. Again, it is undeniably true that if the exhibition of arterial depressants do not abort the disease promptly, then an additional load has been imposed upon the heart, whilst the pathological changes, owing to the fact that this disease rapidly undermines the vital forces, have received new impetus.

To attempt to relieve engorgement of the lung is justifiable, and this can frequently be most safely accomplished by local means, especially cupping and leeching or by the application of the ice box. The excited action of the heart which tends to keep up the pulmonary engorgement may be controlled by the use of morphine which also allays nervous excitement and pain without depressing the central organ of circulation. In sthenic types of the affection moderate bleedings from the median basilic vein would meet the same indications more promptly, and with less danger from ulterior deleterious effect upon the heart than by the use of such remedies as aconite, veratrum viride, antimony, etc.

Prof. H. C. Wood,[1] contends that the administration of veratrum viride bleeds the patient into his own abdomen, leaving the blood to be utilized subsequently when needed; and in this fact, he tells us, lies the advantage of veratrum over venesection. This noted observer admits that this agent depresses the heart, but claims that it does not exhaust it. Now it seems to me that to depress the heart which is already over-burdened, even for a couple of days, must tend to "exhaust it." Occasionally cases are met with in which there is a comparatively large area of lung tissue consolidated with a disproportionately mild type of systemic infection. The heart acts regularly, the first sound is good and the pulmonary second sound is accentuated. In these instances arterial sedations are not so fruitful of evil results, but they recover all the more promptly when the use of this class of remedial agents is omitted.

---

[1] Medical News, January 18, 1890.

In the severer forms of acute lobar pneumonia, the temperature it is well known, is often high and rarely there is hyperpyrexia. The question that confronts us here is, Can we produce the temperature in this disease without increasing cardiac weakness?

Generally speaking pneumonia is a self-limited disease, the crisis being reached usually before the end of the first week. Hence there is little need to attempt to lower temperature in a direct manner in the majority of instances. A temperature not exceeding 140° F. calls for nothing more than frequent cold sponging of the surface and the exhibition of moderate doses of quinine, for example, 16 to 20 grains daily in divided doses. This drug has a slight antipyretic influence whilst it does not depress the heart, but rather supports it. Such internal antipyretics as phenacetine, antifebrin and antipyrin should be rigidly eschewed, since their good effects in combating high temperature is more than counterbalanced by the evil consequences in depressing the cardiac, respiratory, and vaso-motor nerve functions. Very high temperature demands cold to the surface either in the form of cold packs, or cold or gradually cooled baths. This method I have recently followed with very gratifying results. Dr. Bordman Reed,[2] as the result of a statistical inquiry into various modes of treatment,concludes, "That water locally applied either by wet packs or in the form of baths, after the Brand method, is the most efficient single remedy or therapeutic measure for acute pneumonia."

We come now to the consideration of the second causal factor in the production of cardiac exhaustion, or that due to the barrier offered to the pulmonary circulation by the presence of the inflammatory exudate in the air vesicles.

In the first place it may be questioned whether the mere obliteration of a single lobe or even larger mass of lung tissue seriously interferes with the respiratory function, seeing that in animals as well as in man, life may be maintained for a long period after one entire lung has become impervious to atmospheric air. Neither do I believe that the power of the right ventricle would be inadequate if pneumonia consisted merely in a localized inflammatory process. This organ, therefore, is always predisposed to further anatomical changes, on account of the weakening influence of the ptomaines in the blood. It is readily seen then why, in many cases, the backward effect of the obstructive influences in the lungs are evidenced by the development of an overfilled and dilated condition of the right ventricle. The physical signs present, together with the signs of venous stasis, easily distinguish this condition from failure of the whole organ in consequence of intense systemic infection. The pulmonary second sound, which is at first accentuated, due to the strong action of the right ventricle and the strong recoil of blood in the pulmonary vessels, becomes progressively weaker until exceedingly feeble, *pari passu* with the diminution in the power of the right ventricle. This condition of the right heart is associated with an œdematous condition of the lung, and great difficulty with the respiration, as a rule. The complexus of morbid conditions present in these cases is to be relieved by increasing right ventricular power on the one hand, and by removing the redundant liquid from the lesser circulation on the other hand. The latter indication is to be met by the repeated use of wet or dry cups. If in spite of these measures there is a definite increase in the severity of the symptoms, then free bleedings constitute sound practice. Venesection here acts in accordance with ordinary hydraulic principles, and only in this way. To attain to the same end some authors recommend dilating the arterioles by the use of the nitrites, etc., thus inviting the blood from the venous system to the arterial. If it were not for the fact, that in these cases too little blood reaches the left ventricle, the mode of treatment before alluded to should be sanctioned. In my opinion the physician's chief aim should be to propel more blood from the right to the left ventricle, after having removed as much of the obstacle in the lungs as possible, though to accomplish both objects i.e., dilating the arterioles and facilitating the cardio-pulmonary circulation without debilitating the heart would be the ideal treatment. I have recently attempted this, have administered digitalis with a view of increasing the capacity of the right ventricle for work and simultaneously have given small doses of nitro-glycerine for its effect in relaxing the blood vessel walls, with apparently good results. I was lead to use nitroglycerine in consequence of having learned the fact, that, in small doses, it is a cardiac stimulant rather than depressant, and hence, is not open to the same objections which I have urged against arterial relaxants as a class. Strychnia in large doses, and alcohol in moderate doses, must be added to the treatment. Doubtless strychnine is the most potent single agent to support the heart under these conditions. It is most efficient when administered hypodermically in doses of $\frac{1}{40}$ grain every four hours. Inhalations of oxygen are useful in these cases; they relieve dyspnœa and the frequency of the respirations by furnishing sufficient oxygen, in greatly diminished bulk, to ærate the blood. Thus they also accelerate the blood current through the lungs, since it is well known that respiratory impurities in the blood retard the flow of this circulating medium. Oxygen should be employed in this manner when the cyanosis and dyspnœa continue to grow definitely worse despite the use of alcohol, digitalis and strychnine. I have seen truly surprising results from its employment in well selected cases of acute lobar pneumonia in hospital practice.

The formation of cardiac thrombi in the course of the disease constitutes a more influential factor in the production of cardiac exhaustion than is generally supposed by writers on this subject. Doubtless they are often preceded by commencing heart failure, and often, too, are associated with œdema of the lungs.

In acute lobar pneumonia the fibrin factors of the blood are greatly increased; a condition favoring their generation. And, to facilitate the same result, we have the over-filled state of the right heart as well as the sluggishness of the circulation in both heart and lungs. During a recent discussion of the subject of the treatment of lobar pneumonia before the Philadelphia County Medical Society, I took the position that "heart clots" are frequently followed by dilatation of the right ventricle, cyanosis and finally death. Two of the speakers, Drs. S. Solis-Cohen and Judson Daland, subsequently sustained me in this view. Dr. Daland stated that in the course of some examinations of the blood from patients ill of various diseases, he had occasion to examine blood taken from several cases of acute lobar pneumonia; and that when he attempted to examine specimens of this fluid it would coagulate in the capillary pipette with great rapidity, hence requiring special manipulations to make the investigations.

---

[2] Therapeutic Gazette, March and April, 1892.

The symptoms vary with the rapidity of their production. When this is gradual, the signs and symptoms are not immediately urgent; the dyspnœa is increased, the respirations more hurried, the pulse becomes more frequent, finally irregular and intermittent. The physical signs are somewhat peculiar. The cardiac impulse is often irregular, while the area of the heart's percussion dulness extends to a point beyond the right edge of the sternum. On auscultation a systolic murmur is often heard over the xyphoid cartilage, which murmur is transmitted upward and toward the left. The physical signs referable to the right heart may arise independently of œdema of the lungs—a fact which goes to show that heart clots may be, most probably, the starting point of a series of conditions leading to a rapidly fatal issue. Dr. B. Ward Richardson long since directed attention to the value of the ammonium salts in this affection with a view to maintaining the fluidity of the blood; and in this opinion I heartily concur. If there be reason to suspect the presence of thrombi, the administration of the preparations of ammonia, though they offer little promise of giving favorable results, should be vigorously pushed in the hope that the clots may be dissolved.

Alcohol and digitalis are to be employed cautiously, while strychnine is to be administered hypodermatically in full physiological doses; and when collateral fluxion in the lungs with serious respiratory disturbance develop, oxygen inhalations, for the reasons previously adduced, must be employed.

In conclusion, I desire to re-affirm a few of the more salient points already rehearsed in your hearing. To the fact that there are three leading causes of heart insufficiency in acute lobar pneumonia, especial emphasis should, I think, be given. Among these, the baneful effect upon the heart of the toxic matter in the blood is the most pernicious, is a factor in every case, and is not unfrequently the sole cause of death. Cardiac exhaustion due to the action of these ptomaines can be differentiated and presents peculiar indications for treatment, specially useful being antiseptics, alcohol and strychnine.

In a large proportion of cases the right heart, already weakened on account of general infection, becomes further weakened and finally exhausted as the definite result of the obstruction opposed to the circulation in the lungs. In these instances the right ventricle is over-distended and congestive œdema of more or less of the non-consolidated portion of the lung exists. This combination of conditions calls for relief in two directions. First, the removal of the abnormal blood pressure in the pulmonary vessels must be relieved either by cupping or free bleedings; the cardio-pulmonary circulation must be facilitated by using inhalations of oxygen, and strengthening the right ventricle, by administering digitalis generously, strychnine and alcohol. The use internally of the nitrites in small doses is to be advised, while the use of all other arterial relaxants *is to be condemned*, since the agents that accomplish this end tend to depress the heart.

The third, though perhaps, not the most unimportant cause of right ventricular exhaustion, are the cardiac thrombi, which are generated largely in consequence of the sluggish pulmonary circulation and the increased tendency to coagulation of the blood. Their presence is frequently demonstrable during the progress of the disease. For the purpose of preventing their formation preparations of ammonium should be employed, since, as before indicated, they tend to preserve the fluidity of the blood. When "heart clots" of appreciable size exist, and even when their presence is only highly probable, this agent should be exhibited in liberal amount, though as before intimated it is quite doubtful whether the remedy is powerful to liquify these offending masses. Digitalis is to be used cautiously, alcohol in moderate doses and strychnia liberally.

Dr. Bailey, of Louisville, in opening the discussion remarked that he believed the treatment of croupous pneumonia depended almost if not entirely upon the management of the heart. He thought the essayist had given us a most admirable explanation of the heart's action and the course for the proper treatment of the disease. The proper means of reducing the temperature is of the greatest importance. Is there a remedy by which we can reduce it with as little reduction of the heart action as we can by the use of cold water? This preparation he thought we had in phenacetine. He was as willing, he said, to use it in this condition as he was cold water. He believed also that in that condition in which the avenues of the circulation are congested and it is recommended to abstract blood, good results have not been obtained from venesection since fifty or sixty years ago. He commended the ammonia preparations for the conditions indicated but thought they had no power to dissolve clots already formed, although they may prevent the formation of them. He recommended also the nitrite of amyl for opening up the capillaries and getting rid of obstructions, but the principal remedy is digitalis, which he thought was worth all other remedies combined for the relief of obstruction in the lungs.

Dr. Truax, of New York, desired to endorse Dr. Ander's paper, particularly what he had said on the subject of venesection. For a number of years, he said, I have been in the habit of extracting blood in conditions of great embarrassment to the circulation. I have done it experimentally. I have had the internes of the hospital pick out six or seven, or eight of the cases whom they thought most likely to die of heart failure and those who seemed to be the worst, and we have tried different forms of treatment over and over and over again. There is no doubt in my mind that there is any other means by which embarrassment of the circulation in the lungs can be removed and the heart enabled to do its work as by venesection. Stimulants will tide over the heart's action until the congestion is removed. I am sure that hundreds die every year who would be saved if they were bled.

Dr. Herrick, of Cleveland, stated that his line of inquiry would not agree with that of the essayist. He thought we were given too much to theory as to the causation of pneumonia. In this respect he confessed that he was somewhat adverse to the profession as to the theories of the causes of disease. He opposed the bacteriological origin of disease.

Dr. Greenlee, of Kentucky, expressed hearty endorsement and approval of the views of the last speaker. He saw no reason for the supposition that there is a micrococcus!

Dr. Pennell, of Ohio, thought that in some cases you must whip the tired heart up by the use of stimulants, whereas in other cases, venesection must be resorted to.

Dr. Didama, of New York, remarked that Neimeyer and other standard authors state that in some cases the congestion must be reduced by the removal of blood.

Dr. Musser, of Philadelphia, said that this is a subject which demanded from us a clear and full consideration. We ought to have clear ideas on the subject of pneumonia; and the clearer cut our ideas are, the better will we treat the disease. But if we are asked how to treat pneumonia, we can *not* lay down any rule. Our lines of treatment must be based upon the study of the individual case; nevertheless, we can form certain general ideas which we can keep in view. He was thoroughly convinced, and believed that he was in accord with modern pathology, that pneumonia is a specific infectious disease. Such being the case, we turn naturally to the form of treatment which might be considered specific; but such we do not as yet know. We have no specific means of combating this disease any more than we have for the other specific diseases, unless we except malaria. The treatment therefore resolves itself into the treatment of the inflammatory process, and there is no doubt about it that we have only three measures, actual, positive measures that we can always rely upon, for the combating of inflammation. They are cold, bloodletting and rest. Of the importance of cold locally, I am thoroughly impressed. I am also thoroughly in accord with the remarks that have been made on the use of bloodletting. I believe that in almost all cases it would be of advantage. It certainly would not do any harm and it might do a great deal of good. Advantages would arise in almost every case if bloodletting were practiced early. We must, however, be careful as to the indications for bloodletting. We must consider the physical signs, and not only these, but the condition of the pulse, the respiration and the temperature.

Absolute rest is important—not only the rest of the patient in bed, but the freedom from anxiety—perfect nursing is indicated. In securing this complete rest, opiates are demanded. I am always glad to give opium or some of its preparations. Possibly opium may help to allay inflammation as some pharmacologists think.

One word, the speaker continued, with regard to the use of proper remedies. I think that strychnia is a proper remedy, and it may tide our patient over sometimes when they are sailing pretty close to the shore. I am in favor of nitro-glycerine, particularly if there is any tendency to heart failure or chronic parenchymatous nephritis. Of digitalis, I cannot say much. I would prefer alcoholics and preparations of ammonia. Of alcoholic stimulants, we must say that a certain time comes when champagne can be used instead of whisky, and I am sure that the use of this readily diffusible stimulant has stood me in good stead.

We cannot estimate too highly the beneficial effect of good nursing. As to blood letting in the later stages, I am sorry to say that my experience has not been very good. In nearly all of my cases death has ensued in spite of the venesection. Oxygen, I am glad to endorse.

Dr. Anders, in closing the discussion supported the view that pneumonia is an acute infectious disease. In regard to the treatment, he said that so long as we have no specific antidote, we must simply endeavor to support the patient until the disease has subsided.

Afternoon Session.

The only papers read at the afternoon session were those on

THE ANALOGY BETWEEN ACUTE IDIOPATHIC PLEURITIS AND ACUTE ARTICULAR RHEUMATISM.

BY E. L. SHURLY, M.D.,

OF DETROIT, MICH.

In the year 1887, I read a paper bearing the above title before the Michigan State Medical Society, which at the time attracted very little attention. However, subsequent observation of these diseases has led me to think that too little importance has been placed upon this question; and for this reason, I venture now to bring the matter again to public notice.

Attention was first called to this relationship by Vallieux in 1854, and afterwards by Davis, of London, England; but without awakening much thought at that time or subsequently.

In the paper alluded to, the theoretical basis assumed of the identity of the two diseases was mainly two-fold, on the one hand histological, because the pleura as well as the synovial and other serous membranes spring from the same primordial layer, the meso-blast or middle layer, and ultimately develop into the endothelial layer which is the lining of all closed cavities, and, on the other, because a correspondence between the phenomena characterizing the general history of the two diseases seems to exist.

This will become quite convincing if one takes the pains to carefully generalize and compare the various steps in the progress of the two diseases, idiopathic acute pleuritis and acute rheumatic arthritis. Besides, noting how frequently the pleural as well as the pericardial structures participate in the rheumatic affection, I am aware that such a complication of articular rheumatism is not recorded by medical writers as of common occurrence. Yet, I believe, with all due deference, that it is because it is so frequently overlooked, just as syphilitic pleuritis has been, until recently, so generally overlooked; nor would such a mishap appear unusual when we consider how insidious and often localized may be an attack of fibrinous pleuritis. I certainly believe that a retrospective view of the clinical histories of cases of articular rheumatism by any practitioner present would recall certain signs of pleural implication, which, at the time, went unobserved, or were attributed to either secondary or concomitant manifestations, or cardiac complication.

I may mention such complaints as fugitive pain in the side, transient respiratory embarrassment, sudden exacerbations of temperature unattended by increased joint disturbance, etc.

Often, these phenomena are taken as denotive of peri-cardiac or cardiac implication, although close physical exploration fails to recognize the pathognomonic signs. Yet the mind is so intense upon the usual course of events, that failure to recognize the adventitious cardiac sounds, is attributed to lack of auditory power—so strong, in the best of human minds, is preconception.

It occurred to me a few years ago, after listening in vain for signs of cardiac disease in a given case, and when about to give up the search—but not the conviction—that I chanced to place my ear in the infra-axillary region and there detected a slight pleural friction sound, which, of course, determined the diagnosis, and which, I must say was amply corroborated by the subsequent course of the disease.

Besides these considerations we may apply as an additional proof the crucial test of treatment, a practice we are all familiar with, for the purpose of clearing away obscurity surrounding many cases of undetermined syphilitic disease. In this way one may often observe with great gratification the prompt check to the course of acute fibrinous and fibrino-serous pleuritis, and the rapidity with which the effused material is absorbed.

In illustrating the point, I would cite a very serious case which came under my observation lately in association with my colleague, Dr. Chapaton, one of our keenest observers, in which nearly the whole left pleural surface together with the pericardium was involved.

Without wearying you with details, suffice it to say, that under a so-called anti-rheumatic treatment principally—such as the salicylates—the disease rapidly declined in a manner, to say the least, not possible under the established plans of treatment adopted for this disease. In this case there were no arthritic manifestations, until about the tenth day, when the patient complained of pain and slight swelling of the right hip joint and vertebral joints.

In other cases which I have observed, one of the knee-joints seemed to be the elected spot. Although some cases where the pleura was the primary seat of disturbance, never showed any arthitic disease.

Koster, in a late article published in the *Therapeutische Monatschr.* says that the use of salicylates in the treatment of pleuritic effusions has not become as general as it should. He has treated thus thirty-two cases, twenty-seven of which were primary and five secondary. In some of these cases the effusion disappeared in from five to seven days. The results were most favorable in recent cases, although in all but ten the absorption was very rapid. As usual with German writers, he does not mention the observations made in regard to this subject by persons of other countries.

Before concluding there is another point I would like to call attention to, and that is the prevalence simultaneously of acute articular rheumatism and acute iodopathic pleuritis in certain localities. Is it not frequently observed that those regions which furnish many cases of the one disease, also furnish many cases of the other and *vice versa?*

Hereabouts, neither acute pleuritis nor acute articular rheumatism are common. While in districts where one of these affections is common, I have found upon inquiry that the other also is frequently met with.

In conclusion I would emphasize in the first place the necessity for "looking out" for pleuritis in connection with articular rheumatism and *vice versa;* and, secondly, would urge the treatment of acute idiopathic pleuritis mainly upon an anti-rheumatic plan, both dietically and medicinally.

This was followed by a paper entitled:

ADDITIONAL EVIDENCES OF THE VALUE OF FORCED RESPIRATION (FELL METHOD), IN OPIUM NARCOSIS. REPORT OF CASES.

BY GEO E. FELL, M.D., F.R.M.S.,
OF BUFFALO, N. Y.
LATE PRESIDENT AMERICAN MICROSCOPICAL SOCIETY; PROFESSOR OF PHYSIOLOGY AND MICROSLOPY, MEDICAL DEPARTMENT NIAGARA UNIVERSITY; PHYSICIAN TO SISTERS OF CHARITY HOSPITAL, ETC.

It is now nearly five years since I saved my first life by systematically respiring for a human being by forced respiration. Up to the present time nineteen human lives have been saved by this means. The method has been given as great publicity as possible by publication in well known medical journals and proceedings of societies. The fullest detail as to the arrangement of apparatus has been described, so that the successful methods could be utilized and the apparatus prepared by any one sufficiently interested. I have always been willing to aid and assist any one disposed to utilize the method. The most simple means by which the operation could be satisfactorily performed have been detailed, with a view of aiding the practitioner in urgent cases where the complete apparatus could not be obtained. However, what results have been accomplished as already stated, the saving of nineteen human lives, have with few exceptions taken place through my own individual endeavors. Many human beings, as the reports of the daily press have indicated, have been forced to cross the "Styx" when preventive means existed which the members of the medical profession could have utilized, had they taken advantage of the statements and facts freely presented to them. It may not be entirely truthful to state that the medical profession in America is ultra-conservative regarding the use of "new methods," in the face of the wild furor over tuberculin, or the Brown-Séquard elixir. The latter quickly settled itself, and the former the best authorities now appear to discredit as anything of a specific for tuberculosis. How has it treated forced respiration, in its success an entirely American idea, and which from the first intelligent application gave results that could not be questioned by even those inclined to be jealous and unfriendly? It has not even been made the subject of special comment in the medical institutions of the day; so that the graduates in medicine of but few colleges in the land are intelligently qualified to carry it out, and medical practitioners are not prepared to use it or apply it when supplied with the apparatus. This was quite interestingly demonstrated in a case (No. 25) which was presented not long since, at a time when I was unable to attend, and sent my young nephew with the apparatus to assist two regular practitioners in the saving of a human life from opium narcosis. Although both residents of my native city, and the methods of forced respiration being very simple, these gentlemen were not sufficiently well acquainted with the simple details of the apparatus to use it intelligently. My student, a young man about 16 years of age, having seen it frequently in use, assumed charge, and saved the lady by his efforts. I only speak of this to show that simple methods require more or less study and consideration on the part of any one, even capable physicians, who desires to use them intelligently; and I deprecate most fully the assertion of Horatio C. Wood, that any method upon which the life of a human being may hinge, may be used by "unskilled persons." Simple as forced respiration may be—and in this consists its greatest value to mankind—the saving of the life of many human beings has been accomplished in my hands, only by the skilful use of an apparatus specially adapted in detail for use upon man, and through practical knowledge which it has taken me some years to become satisfactorily acquainted with.

Another instance which indicates that medical press notices and publication in State Association Transactions will not suffice to impress upon the profession the value of forced respiration as a life-saving factor, was instanced in the case of Carlyle W. Harris, convicted of the murder of his young wife, Helen Potts, through the administering of morphia in fairly large doses. In one report of the case, it is claimed that young Harris desired or suggested to the physician who was attempting to resuscitate the young woman, that he make tracheotomy, having a vague idea only of its use. The physician appeared to know nothing about the method. In this one instance I have no hesitancy in stating that the life of the young woman could have been saved by my method of forced respiration, and in the event of the execution of Harris, we will have to record two lives lost through what will be some of these days almost criminal ignorance of physicians.

The public press is almost daily recording cases of death from narcotic poisoning or from drowning, in which the old methods have failed. Why not try something better, which has succeeded time and again where they have failed and must frequently fail?

Regarding the question of originality of my methods, I wish to again pay my respects to Prof. H. C. Wood, as he has given the impression through his statements before the Berlin Congress, that the apparatus I used was similar to that used in the laboratory upon lower animals, so that Dr. John O'Dwyer, of New York, has given public utterance to the statement which Dr. Wood first, and I think unwarrantably, urged. In an article in answer to Dr. O'Dwyer, on the improved method of performing artificial respiration (see *Archives of Pediatrics*, May, 1892), I show nine marked practical features of difference between the apparatus which I have used successfully and the laboratory apparatus with which I saved my first life by forced respiration. I quote from my answer as follows:

"That used in my laboratory[1] before I devised my forced respiration apparatus for use upon man, consisted of a large foot bellows, a rubber tube to connect it with a large brass tracheotomy tube supplied with a valve, which had to be turned by hand to let the air pass into the lungs, and turned in the opposite direction to let it pass out.

"With this arrangement, each time the valve was turned, for the inspiration as well as the expiration, the trachea was given a wrench. I have found that it makes a great difference whether you are wrenching the trachea of a dog or a living human being. I overcome this feature of the laboratory apparatus by making my tracheotomy tube and the valve which controlled the air column in separate parts, connecting them by flexible rubber tubing. This would permit the patient to move about without endangering the trachea. This may be noted as the first feature differing from the laboratory apparatus.

"In the laboratory apparatus the trachea had to be ligated around the tube as Dr. O'Dwyer states, but *not so* in my apparatus. To prevent this, I screw to the tracheal end of the tube a larger or smaller ring, according to size of the trachea, which fills up the trachea, preventing an excess of air passing out by the side of the ring.

"This is the second novel feature of difference from laboratory methods.

"Again, I made the connection between the flexible rubber tube and the tracheotomy tube so that it could be easily and quickly disconnected. This is an important feature, and constitutes the third feature of difference between my own and the laboratory methods.

"The valve which controls the air also has some valuable features. 1. With it, the air can pass into and out of the lungs at all times, except during the forcible inspiration. Fourth and fifth differences from that of the laboratory apparatus. 2. The air from the bellows is constantly passing through the valve during expiration, thus allowing the air to immediately enter the lungs from the air valve when the piston is pressed down, without traversing the whole length of tube from bellows. Also, by the removal of the thumb from the piston of valve, the expiration takes place immediately, without any counter air current from the bellows. With this arrangement, auto-respirations can be assisted instead of interfered with, a factor of importance in many cases I have met with.

"This makes the sixth and seventh differences between my apparatus and that used in the laboratory.

"In the construction of the bellows I used a diaphragm of rubber dam (now a double bellows without perishable rubber), which equalized and produced a steady, instead of an interrupted or jerky column of air, such as Prof. H. C. Wood provides in his so-called 'cheaper apparatus,' with common bellows. Here we have the eighth difference between my own and the laboratory apparatus.

"If I wish to present still more features of difference, I might include the air heater, which I also have practically used upon cases of resuscitation of human beings. The eight features of difference mentioned above will, I trust, put a *quietus* upon the question of similarity between my own and the laboratory apparatus. What I have accomplished has resulted from *careful attention* to the details of *practical import* associated with an operation which holds human life in the balance, not by *slipshod* methods which have in the past relegated this operation to oblivion, and which methods some are now trying to revive. If the saving of eighteen human lives, the record of results with which my work must so far be credited, is not an argument in support of my statements, what 'under the stars' does or will give credence to human utterance? However, I have overlooked another similarity between the laboratory apparatus and my own, the face mask. Of course the face mask, every one will admit who knows nothing about it, was used in the laboratories in the days of Galen. Without joking, however, this constitutes the ninth marked difference between the laboratory apparatus and my own, and yet Dr. O'Dwyer does what appears to me an injustice, in speaking of the two as being identical. I desire to state that, notwithstanding an experience in laboratory vivisection work for eight years prior to my first operation of forced respiration upon man, it was not until this first operation that I was enabled to conceive its great value. All my experiments, the gradual unfolding through operations upon living human beings of the value of the face mask, should give weight to my words above those resulting from *experimentation upon dogs;* the conditions are very different. All that experimentation *upon dogs* has revealed as to the value of forced respiration in saving life I had previously demonstrated upon living human beings; when I began my work it was not even known that it would save a dog's life. Now a few words with reference to the evolution of the face mask. I had begun the operation of tracheotomy upon one of my patients, when my attention was called to the fact that he was dying, the dilatation of asphyxia taking place. I immediately placed the tube of the apparatus in his mouth, closed the lips about it, and compressed the nostrils; inspiration then being produced, I was pleased to find the purple deoxygenized blood in the tracheotomy incision change to a bright scarlet. I had many demonstrations of this character following, which gave me the idea of the face mask. Having a rubber cup used for cupping purposes, I fitted it to the face and saved several lives with it without tracheotomy before preparing the one I now use."

While the description of an instrument may appear somewhat detailed, and indicate that the method in operation is somewhat difficult, such in this instance is not the case. All there is to forced respiration is the forcing of air under suitable pressure and control, with proper periodic intermission, into the lungs. It can only be properly done with suitable apparatus. The simplicity of the method should give to the operation its widest range of usefulness; but to become practically acquainted with it one must see it, and study it before he can understand it. With proper instruction, the members of a life saving, or a ship's crew could be taught to utilize this valuable method of saving human life. I presume before the "conservative" (?) medical profession of America will utilize this method, that thousands of its members must have their attention *specially* called to cases of resuscitation through its employment.

---

[1] Medical Department Niagara University, Buffalo, N. Y.

Another matter I may refer to at this time: I believe all will admit that the greatest credit which it is possible to obtain as the originator of a method of wide range of applicability in saving human life, consists in the largeness of the list of lives saved by it, and the just appreciation of its value by your fellow man. There is no higher aim that we as physicians can conceive, than that of preventing the vital spark from taking leave of the human organism. If this be true, it does appear unjust, unfair and unthankful that credit should be withheld from those who are entitled to it, and the medical world, in any section, use these methods without the greatest care in giving to those justly entitled, the credit due them.

This is the only payment which the profession allows those who accomplish results of *value* in fields unexplored. On this account, therefore, the original labors of physicians should be guarded with the utmost care in all sections of the globe. The following quotations (with additions) from a paper presented before the last meeting of the New York State Medical Association, will explain my reason for the above remarks:

"Through the kindness of Dr. Thos. H. Manley, of this Association, I am enabled to refer to an article in the Proceedings of the Paris Academy of Medicine, under date of June 2, 1891, in which Dr. J. V. Laborde, in a discussion on 'Anæsthesia' regarding the dangers of chloroform narcosis, recommends forced respiration, and has devised a face mask with which to perform the operation. This face mask is of metal, with the edges surmounted or faced with rubber, and includes the nose and mouth. It is, to 'all intents and purposes,' similar in detail to the one I have been using for some years, and with which I have saved a number of lives. Dr. Laborde speaks of his invention as novel, of great future value, declaims on the subject never having been brought up for discussion, etc. All the members of this Association, who have been acquainted with my work for the last four years, will agree that our Paris physicians can well afford to look Westward to learn that progress is not confined to Continental Europe. It is quite strange, also, that Dr. Laborde has overlooked the statements of Prof. Horatio C. Wood, in his address on 'Anæsthesia' before the Berlin Congress, 1890, in which he distinctly calls attention to my face mask, and which I had been using for two years previously.

"I am also astonished by the statement in the Paris Academy report, that noted French physicians have been using my method by tracheotomy with remarkable success, and without giving any credit for its practical introduction to the world from this side of the Atlantic.

"At the Paris Exposition of 1888, which had a department to illustrate life saving methods, one of my instruments was exhibited by Mr. George M. Bailey, of Buffalo, N. Y., who, having witnessed the remarkable case of Julius Barre, in which instance I respired twenty-four hours for my patient before he was able to breathe for himself, requested, in the interests of progress, the privilege of taking it abroad. He had with him reprints of my articles published in the Transactions of the New York State Medical Association, which were distributed among some of the physicians and jurors interested officially in the Exposition. At *that time*, through ignorance of the value of my method, they took no notice o my work as being worthy of note as a life saving invention. Even the representative of the United States Government at the Paris Exposition did no see anything of value in it, although no more remarkable cases are recorded in the annals of medica science than some of the first reported in my memoir *which were placed at the command of these gentlemen*, but possibly not given the attention they deserved; but appropriated it, utilized it, and no claim originality for methods which I had previousl used and first recommended in practical shape to th medical world."

The last case reported to this Society illustrate that forced respiration may be utilized as a tiding over measure, and was reported in THE JOURNAL o the Association July 11, 1891. A number of interesting cases have taken place since, which are briefl described as follows:

Case 20.—In the surgical clinic of Dr. Hal. C. Wyman Detroit Emergency Hospital Reports, reported by Dr. Robert S. Linn under Fell's Operation for Morphine Poisoning as follows:

"Miss C., æt. 21. Had taken 20 grs. morphiæ sulph. abou one hour before ambulance was called. Her condition whe brought to Emergency Hospital was critical. Pupils wer *much contracted, and did not respond to light. Respiratio were only five a minute and pulse quite weak.* The stomac was evacuated of its contents with stomach pump, and abou one pint of strong coffee injected into it. About 16 ozs. urine were drawn from the bladder. A hypodermic inje tion of atropiæ sulph. (grs. 1-60) was given, and artifici respiration performed without benefit. An incision 2 inches long was made in the median line over the trache *tracheotomy performed, forced respiration kept up* f about three hours, and the life of the patient saved."

Case 21.—Dr. Fell, Buffalo, N. Y. I was called by Dr. E H. Long, to attend a case of opium narcosis in a lady years of age. She had taken a large quantity of gum opiu Respirations shallow, fourteen per mihute, pupils con tracted, coma existing. Face-mask applied, and use about eleven hours, when tracheotomy was made, but t late to save the patient. Convulsions set in, and conti ued uninterruptedly until death ensued. A mistake w made in this case in not performing tracheotomy earlie With the face-mask the cyanosis was not satisfactorily ove come. Extension of the head, which was used with succe for a time, had finally no influence in raising the epiglot A ligature through the tongue, by which the base of t tongue was raised, worked better. The cerebral hemispher were greatly congested. Free venesection would have bee beneficial if performed in season. The indications for trach otomy existed for some time before it was made.

Case 22.—Dr. Fell, Buffalo, N. Y. I am under obligatio to Dr. Allen A. Jones, Instructor in Practice, Medic Department University of Buffalo, by whom I was called, f the following report of this case, in which the face-mas demonstrated again its great value in a typically approp ate case:

"About 4 o'clock on the afternoon of Thursday, October 1891, I was hurriedly summoned to the house of a form patient, and found her lying on a sofa unconscious,extreme cyanosed, her lips and ears being blue; her pupils were co tracted almost to pin points, and her respiration was of t Cheyne-Stokes character, ceasing entirely for two or thr full minutes, *then coming with peculiar groanings* a whistlings which died away until respiration ceased.

"I had been told over the telphone that she had tak morphine, but I did not know how much.

"Her pulse was frequent and small, but yet of go strength when I first arrived. I sent for Dr. George E. Fe without delay, with instructions that he should bring h apparatus for performing artificial respiration.

"While awaiting his arrival, with the help of those abo me, I succeeded in restoring some color to the lips by ar ficial respiration (Sylvester's method). The pulse gre weaker and weaker, and the heart almost ceased beati before Dr. Fell arrived.

"It was impossible to give emetics per orem, so we gave one-fifth of a grain of apomorphine hypodermically, as soon as Dr. Fell arrived. Then with the patient on a table we instituted forced respiration (by face-mask).

"The patient's lungs filled easily and well without tracheotomy.

"We breathed for her steadily for about one hour, and then she moved her hands to her face and opened her eyes. Her cyanosis had entirely disappeared, and good oxygenation was manifest. The face-mask was taken off, and the patient breathed for herself in a long, slow, sighing fashion several times, but ceased entirely at the expiration of a few minutes. The lips turned blue once more, and she would inevitably have died had we not recommenced forced respiration again. Very soon she was again able to breathe alone, and temporarily stopping the forced respiration, we gave her mustard water, and she vomited profusely. We repeated the mustard water, but she did not vomit; her head fell back, respiration ceased, and again she was turning blue when we applied the face-mask and used forced respiration for the third time.

"After a short time we succeeded in inducing her to swallow another large cupful of warm water and mustard with a teaspoonful of salt in it, with the result that she emptied her stomach completely.

"As is common in conditions where the respiratory center is benumbed, emesis seems to stimulate the centre, and respirations were more willingly taken. Even at this junction, however—being about two and one-half hours from the time that forced respiration was commenced—she would certainly have died had it not been continued, as it was, altogether for four hours. At the expiration of that time, she breathed herself seven times in the minute, and in the morning her respirations were 20, her pulse 80, temperature 101.

"Dr. Herbert U. Williams, who kindly remained all night with the patient, stated that the pulse gradually fell, and the respirations gradually increased, from hour to hour, that he gave her a hypodermic of atropine (1-150 of a grain), of strychnine (1-60 of a grain), and of tincture of digitalis (15 drops) about 11:30 P. M. At 1:30 A.M. she had a cup of strong coffee, and a glass of warm milk at 2 A.M. At 2:30 A.M. she urinated freely.

"This patient said she took eleven grains of morphine dissolved in a glass of water at 1 o'clock on the 8th. I saw her at 4 P.M.; Dr. Fell arrived about 4:30; we performed forced respiration until 9 o'clock with the result that the woman's life was saved.

"I am convinced that ordinary artificial respiration would not have saved her life, and I cannot speak in too high praise of Dr. Fell's effectual and simple apparatus for forcing such a patient to breathe, if necessary, for many hours in succession. I think more physicians ought to possess and have in readiness Dr. Fell's apparatus, and many lives would be easily saved, where now they are lost because no such facility is at hand.

"It is interesting to note in this case that diplopia existed from the return of consciousness on Thursday evening until sometime Saturday morning: and for four days the patient thought a cup of food, or whatever it might be, in her hand was held at the lips, when in reality it was four inches from them, and at first she poured out milk and tea upon her dress."

Case 23.—December 1, 1891. Called to Erie County penitentiary by Keeper Albert H. Neal. Geo. C. W., a prisoner, had taken tincture of opium, 3 oz., and a quantity of sweet spirits of nitre, with suicidal intent at 1 P.M.

Grains .1 apomorphia hypodermically administered by Drs. Fohl and Hays, resident physicians, produced vomiting. I reached the case at 3:10 P.M. The conditions usually produced by the poison were present. After about one half hour's forced respiration work per the face mask, the cyanosis prevailing passed away; heart action became stronger, and patient became conscious at short intervals of time. This condition prevailed under forced respiration for some four hours, then auto-respiration ensued. The stupor was unusual, and I ascribed it to the intense congestion of the encephalonic vessels. Death I believe has been caused in several of my cases by this condition. At my request Drs. Fohl and Hays removed 4 oz.. of blood from the left arm with quite satisfactory results, relieving the congested state, and aiding I believe very much in the saving of the life of the patient. This patient was put to bed before I left the case, and was apparently on the fair road to recovery. Some few days later to my great surprise I noticed that he died of heart failure. I had not seen him since my operation, although informed that he had progressed favorably until the time of his death, which occurred suddenly. The next case indicates, as this does also, the importance of sustaining treatment and careful watching of the patient for a few days at least following the operation.

Case 24.—Mr. C., a resident of Niagara street, Buffalo, a man not habitually accustomed to drink, came under the influence of liquor under peculiar circumstances, and is said to have taken 2 oz. of laudanum. He was taken by the ambulance to the Fitch Hospital, and treated in the ordinary manner by the surgeons in attendance at the hospital, but with unsatisfactory results. The wife and brother-in-law were called about 11 P.M., and they were informed by the physicians in charge that there was no hope for the patient; that everything had been done that was possible to be done. At the urgent request of the wife of the patient I was called about 11 P.M. I found the patient in a very precarious state, totally unconscious, and in danger of death supervening quickly.

I applied the forced respiration apparatus with favorable results. The cyanosis was overcome, and after some four hours' work the patient became conscious, respired for himself, and at 6:30 in the morning was taken to his home in the ambulance. A condition of stupor continued at his home for a number of days following the operation; he did not seem to improve as rapidly as was the custom until he was taken to a neighbor's house, when it was noticed improvement was rapid. He had been placed on stimulating and supportive treatment, but with apparently very little success. It was noticed, however, that there was quite an escape of natural gas at the stove connection in the room in which he lived, and very much of his slow recovery must be attributed to this, as after removal from the house he recovered very quickly, and on the leak in the pipe being repaired he was not further affected, and made a good recovery. This case illustrates the importance of hospitals being provided with an apparatus suitable for performing forced respiration. Had it not been for the special request of the wife of this gentleman, who was very devoted indeed, there is no question but that he would have died under the treatment used by the physicians at the Fitch Hospital. All had been done that artificial respiration or ordinary methods would accomplish, and yet within four hours from the time I was first called to see this patient he was placed out of a dangerous condition. The question arises whether, with such facts presented to the profession any hospital in the country is justified in not being prepared for cases of this character, which may at any time be presented to them.

Case 25.—Mrs. W., of Ellicott street, Buffalo, took an overdose of morphia. I was sent for, but was unable to attend owing to illness, and sent my apparatus in charge of my office student, a nephew 17 years of age. The case was reported as hopeless under the ordinary treatment, but quickly succumbed to the forced respiration per face mask. and made a good recovery. (See remarks page 130.)

At the next meeting of this Association, I expect to be able to present steam and electrical apparatus available in forced respiration and demonstrate with artificial lungs the various points urged in my papers upon this subject.

I would be pleased to have reports of cases which may occur sent to me at Buffalo, N. Y., and will incorporate them in my general report giving full credit to whomsoever will kindly act on these suggestions.

THE LOUISIANA STATE MEDICAL SOCIETY at its recent meeting elected the following officers: President, J. B. Elliott, Orleans; Vice-Presidents: First Congressional District, P. E. Archinard, Orleans; Second Congressional District, A. W. DeRoaldes, Orleans; Third Congressional District, A. J. Perkins, Calcasieu; Fourth Congressional District, J. W. Allen, Caddo; Fifth Congressional District, T. J. Turpin, Madison: Sixth Congressional District, J. S. Branch, Avoyelles. This committee on nominations recommended that New Orleans be made the permanent meeting place of the State Medical Society, and that the second Tuesday in May, 1893, be the date of meeting, and *furthermore, that the* secretary and treasurer be paid an honorarium of $150 in recognition of their faithful services.

THE degree of LL.D. was conferred on Dr. John M. Keating, of Philadelphia, by Seton Hall College.

THE NECESSITY AND BEST METHODS OF REGULATING THE PRACTICE OF MEDICINE.

Read before the American Academy of Medicine, at Detroit, Mich., June 6, 1892.

BY PERRY H. MILLARD, M.D.,
HONORARY MEMBER OF THE AMERICAN ACADEMY OF MEDICINE, DEAN AND PROFESSOR OF THE PRINCIPLES OF SURGERY AND MEDICAL JURISPRUDENCE, UNIVERSITY OF MINNESOTA.

Gentlemen: In reviewing the question of medical education in the United States the student of history will readily conclude that the facilities afforded pupils of medicine have been painfully inadequate, and that the minimum of requirements in a vast majority of colleges have been well below that standard which affords the public a profession possessing a degree of skill and ability commensurate with the safety of its people. It has been the policy of the authorities controlling these institutions of learning to maintain a standard below recognized safety. In addition to the very low curriculum, the resources of most colleges have been inadequate, and the clinical instruction most deficient. It is but recently that a majority of the colleges in this country have attempted a system of regular laboratory instruction. A study of the causes leading to this dilemma are many; among the most frequent may be mentioned the following: First, the history of pretended medical education in this country covers a period of little more than a century. The people possessing those elements of hurry and restlessness observed in all new communities.

Secondly, it has not been the policy of this government to liberally support university or higher education; a form of education reaching a high degree of perfection in the British Isles and Continental Europe, and embracing in its scope all special lines of advanced instruction, such as law and medicine.

Thirdly, the people being governed by a republican form of government, the policy has naturally been liberal in respect to freedom of action and choice of avocation; not infrequently this policy has been at a sacrifice of the best interests of a credulous public. In a monarchical form of government it is very much easier to restrict or control the action of its people.

Fourthly, in consequence of the late Civil War covering a period of four years, a half million young men found themselves penniless, with limited education and without avocation or a profession. Many thousand had secured a superficial knowledge of the art of medicine and surgery, from their war experience, and naturally, as a result, a horde of brave but uncultured men turned their attention to the profession of medicine. In consequence, the number of medical colleges in the United States doubled in a short space of time, and the list of matriculates increased at a much greater ratio. Notwithstanding the wonderful increase in population and resources of this country, in a period of a few years the proportion of physicians increased far beyond the legitimate demands of the public.

Fifthly, there has been a noticeable absence of that concert of action so necessary between the different schools of instruction to secure uniformity of system in education, or uniformity in the attempts at the elevation of the standard of medical instruction. There has been no restriction to the unlimited multiplication of the number of medical colleges. There has been no attempt to dictate the character of instruction by legislative control. There has been but little attempt to regulate the character of instruction even by the faculties themselves. In consequence thereof, the profession and public in the last few years have been casting about for a means or remedy to avert a disaster that seemed to imperil the very existence of the noblest of the learned professions. It became apparent to the observing and thinking that the profession of medicine was being degraded in its personnel, and but little respected by the people themselves. A condition was fast approaching whereby we were placed in quite as ridiculous a position as is described by Moliere in the fourteenth century. It required but a casual study of the situation at this time, to conclude that but one of two methods were available for the correction of the present evil. The first was, that the power to raise the standard of medical education in the United States was vested wholly in the various faculties of medical instruction and by concerted and business-like action they could readily comply with the most reasonable demands of the profession and the public, and in doing so, not materially injure their own interests in bringing about the much needed reform.

Secondly, that in failure thereof, the only alternative was in a resort to some restrictive legislation compelling the various colleges to raise their standard of instruction, both as applying to their preliminary entrance examination and curriculum of professional study. A sincere attempt was made by representatives of a few colleges in a period of time from 1876 to 1882, and there resulted from this effort the lamentable history of the American Medical College Association. The disruption of this Association was brought about by the treachery of a few representatives of colleges whose policy was governed entirely from a commercial basis. The disruption of this Association at the time was considered a great professional calamity, and the friends of higher medical education soon cast about for some method of bringing order out of chaos.

It was determined that the best means of controlling this evil was through efficient medical legislation. As a result members of the profession scattered throughout different portions of the country attempted to secure legislative enactments creating State boards of medical examiners. In a majority of these instances the attempts were met with defeat at the hands of the different legislatures, and a majority of the bills that had become laws were painfully defective, as could only be expected in any new form of legislation. The first act that was recognized as being efficient, and at all restrictive, was that of the States of Illinois and West Virginia. Immediately following we have substantially the same act in force in the States of Missouri, Iowa, Minnesota and Dakota.

This form of legislation permitted men to become legal practitioners by submitting a diploma issued by a regularly chartered medical institution. The act further provided that diplomas may be refused or revoked for unprofessional or dishonorable conduct.

The profession soon recognized and were convinced that the so-called Illinois act, if properly enforced would exercise a wholesome and restraining influence upon medical colleges and rid the public of the infamous practices of the itinerant charlatan. Those of us whose painful duty it was to enforce the above named medical law, know too well, the Herculean task we had undertaken. The barriers seemed insurmountable, and our only solace was the realization that our cause was just.

It was my province to act as Secretary of the Minnesota board for a period of five years, or during the life of the first practice act. This act was substantially a copy of the act now in force in Illinois and several other States.

My experience and observation soon convinced me that we had upon our list of recognized colleges a large number of schools whose alumni were not safe practitioners. Any attempt to discipline these institutions was met in a most belligerent spirit, or by an influence well suited to the ward politician or political black-mailer.

I became firmly convinced that the principle of recognizing the diploma of colleges was not the correct one. I soon agitated the propriety of the amendment or entire repeal of the Minnesota act, or the securing of a new act calling for a personal examination of each and every person wishing to practice medicine in the commonwealth. The propriety of determining the fitness of men to practice medicine by means of a personal examination was recognized and acknowledged to be the proper method by the State Board of Minnesota. At a conference of Boards of Medical Examiners held in Chicago, in 1885, I urged the propriety of concerted action in an attempt to secure uniformity of legislation by an act in the several States, calling for an examination of each candidate for a license and providing, as in the Illinois act, the privilege of refusing or revoking licenses for unprofessional or dishonorable conduct. The concensus of opinion at this conference plainly indicated that it would be a step in advance, if we possessed legislation granting the privilege of examining all students wishing to commence the practice of medicine. The majority of those present, however, were of the opinion that the opposition would be so pronounced as to ensure defeat. The members of the Minnesota Board, however, concluded to ask the legislature for further legislation, and I was instructed to draft a bill for submission at the forthcoming session. The bill was the same as the one now in force in Minnesota and several other States. It became operative with us July 1, 1887. It established a minimum of time to be spent at medical lectures before a person would be permitted to apply for an examination to determine his fitness to practice medicine. It further provided for an examination of all persons wishing to commence the practice of medicine in any of its branches in the State. It likewise granted the privilege to refuse or revoke licenses for unprofessional or dishonorable conduct.

It was the first draft of a bill to become law which called for a minimum of time to be spent at lectures before commencing the practice of medicine. This feature of the bill has proven eminently satisfactory in Minnesota, and has been copied in the statutes of several other States. Its effect has been most salutary upon several of the medical colleges of this country, and as a result thereof, nearly every institution of this country whose term of lectures were less than six months have extended the duration of the same to comply with the statutory requirements of these States. At the present time, parties wishing to commence the practice of medicine in the following named States are required to prove their fitness therefor by undergoing an examination: Minnesota, North Dakota, Montana, Washington, North Carolina, Alabama, Florida, Virginia, New Jersey, New York, Nebraska, Maryland and Utah.

Nearly all of this legislation has been accomplished in a period of the last five years, and the present indications are that in the near future a majority of the States of the Union will secure quite adequate legislation. The agitation of this reform has met with quite bitter opposition from some sources; the principal opposition, however, coming from the authorities of the various medical colleges. This opposition has been most futile, as the situation of the profession in this country was readily recognized by the legislators, and because of the further fact that no rational argument could be rendered against the constitutionality or propriety of some form of restrictive legislation.

The necessity of restricting the practice of medicine has been recognized by all nations of civilized people from time immemorial. Every European country possesses most stringent practice acts and have for centuries. The so-called police power has likewise been recognized for centuries.

Traces of forensic and state medicine are as old as institutions of civil society. The Jews recognized mortal wounds. The Egyptians provided that no woman pregnant with child should suffer afflictive punishment. The Romans even from the period of Numa grounded many of their laws upon the authority of physicians. The Caroline Code, under Charles V., was established in 1532. The first traces of the exercise of police power as applied to the practice of medicine is found in Italy, in 1237. Here a license to practice was granted by the University of Salino after a study of philosophy for a period of three years and of medicine for a period of five years. This license was only obtainable after undergoing a satisfactory examination. Shortly after this date licenses were likewise granted in England.

The first degrees in medicine were presumably granted in 1384. The first efficient law regulating the practice of medicine in England was enacted in 1511. The progress of medicine during the seventeenth century has been ably described by Macauley in Volume 1, Page 310 of his history.

"Medicine," he says, "which in France was still in abject bondage and afforded for Moliere an inexhaustible subject of just ridicule, had in England become an experimental and progressive science, and every day made some new advance in defiance of Hippocrates and Galen. The attention of speculative men had for the first time been directed to the subject of sanitary police." An investigation reveals the fact that efficient regulation of medical practice and higher medical education progressed, hand in hand, from the period of time mentioned by Macauley down to the present time. The courts have universally affirmed the legality or constitutionality of the various laws regulating the practice of medicine in the different countries of Europe. In this country, the United States Supreme Court has recently rendered a decision affirming the constitutionality and general features of medical practice acts. A large number of the Supreme Courts of the different States have likewise affirmed the constitutionality of the different medical practice acts. In a few instances, in the lower courts, where decisions have emasculated the power of State Boards of Medical Examiners, it has been due to the faulty wording of the act itself, rather than to any unconstitutional features that may be found in this form of legislation.

In a paper read by me at the session of the American Medical Association, held in 1888, I advocated a greater uniformity of medical legislation by the various States. This discussion lead to the appointment of a committee, with instructions to formulate the general features of a practice act that would be suitable for adoption in any of the different States of the Union. As chairman of that committee, I submitted the draft of a bill at the next session of the Association possessing the essential features of the act now in force in the State of Minnesota. The report of the committee was unanimously accepted and adopted, together with resolutions urging upon the profession of different States the propfiety of at once attempting the establishment of efficient medical practice acts in the different States of the Union. I am gratified to observe that in nearly all instances where medical practice acts have recently been obtained, the essential features of the Minnesota act have been adopted.

The question of medical legislation should be considered from two standpoints, to-wit: That of the regulation of medical practice, and the regulation of medical education. In the performance of the first function Boards should consider that it is simply their duty to protect the public from the imposition of charlatans, and the grave errors certain to arise from the practices of uneducated men. The duties of the State Licensing Board end here. If the act is so worded as to likewise regulate medical education in the commonwealth, it is eminently proper that a minimum of requirements should be established, and the Boards authorized to exercise a general supervision pertaining to the character of instruction in all colleges whose alumni become applicants for the privilege of practicing in the State. I sincerely question the propriety of one Board performing both of these duties. Basing my opinion upon extensive observation and experience, I believe that the best interests of the public will be subserved by assigning the duties of the State Licensing power to the various State Boards of Health. The Medical Licensing power is purely a police power, and were these duties assigned to Boards of Health, it would assure greater prestige and influence in the community. I believe the regulation of all forms of education should be vested in a central power consisting of a single Board to be known as a State Bureau of Education with power to regulate all educational institutions granting degrees, together with the power of granting charters, and revoking the same; particularly should this apply to all institutions wishing to afford the community any of the various forms of higher or special education. Under existing circumstances, in a vast majority of the States of this country, three or more persons can form a corporation, and become incorporated by application to the Secretary of State and grant degrees *ad libitum*. Of the personnel of these Boards it is immaterial providing the parties be reputable and intelligent practitioners of medicine. It is my opinion that the mixed Boards, such as exists in Minnesota, Illinois, Iowa, Montana, Missouri, North Dakota and several other States of the Union, render better service to the public than in the few instances where separate Boards have been created in compliance with the demands of the several schools of practice. In the States possessing mixed Boards who conscientiously perform the duties of a public servant, I have yet to hear of any clashing or jealousy among the members thereof. I believe the best interests of the people will be subserved by the maintenance of a clause in each of these acts providing for the refusal or revocation of a license to practice when guilty of unprofessional or dishonorable conduct. I question the propriety, however, of Boards exercising this power except in most flagrant cases.

If John Smith is disposed to occupy the first page of a newspaper in calling the attention of the public to the fact that he confines his attention entirely to diseases of the genito-urinary organs, I believe this indiscretion alone should not cost him the right to practice medicine, upon the contrary, should he claim in the public press that he can cure what is recognized by the profession as an incurable disease, such as consumption or cancer, it is the duty of the Board to step in between the credulous public and the dishonorable practitioner and deprive the impostor of his professional rights. It is, likewise, the duty of the Board to refuse or revoke a license for persistent and chronic inebriety, criminal abortion and repeated gross immoralities.

As honorable and intelligent physicians, we recognize the great sin of advertising in any manner. In view, however, of the outspoken sentiment in favor of any restriction in this direction, I presume it is better to allow the fool his course, at least until he reaches that point in his career that his practices imperil the safety of the public.

I am pleased to submit some statistics of the work accomplished by several State Boards of Medical Examiners. My statistics are from States where the law requires a personal examination of the applicant's fitness to practice. These examinations include all the essential branches of the field of medicine. They afford a most convincing argument in behalf of efficient medical legislation.

I trust I may not be considered presumptuous if I assert that in the administration of their delicate and untried trusts, it has been the policy of these Boards to be somewhat lenient, and to license many whom they knew possessed very inadequate instruction. A part of their duties have been to educate both the profession and the public to the propriety of this form of legislation. Notwithstanding this policy we are informed that 24.8 per cent. of all applicants for a license to practice have been rejected as unsafe practitioners.

My statistics are based upon returns from the following named States, to-wit: Alabama, North Dakota, North Carolina, Virginia and Minnesota. Table number one indicates the number of different persons, examined, passed, rejected, percentages, etc. Total number examined 1950; total number classified, 1746; total number unclassified, 204. The unclassified represents foreign and extinct colleges and undergraduates. Total percentage licensed .752 per cent. (Table No. 1 not published owing to space required.)

The following data are compiled from the records of the different Boards of Examiners. The comparison indicates the result of the examinations of graduates of the graded three course institutions and those that previous to 1890 conferred degrees after attendance upon two courses of instruction. The above

TABLE II.

The following table indicates the result of the examination of 183 students, graduates of colleges requiring three courses of instruction before receiving the degree of M.D.:

State.	Univ. Penn.		Univ. Mich.		Univ. Minn.		Harvard.		Chicago Med.		Col. Phys. and Surg. New York.	
	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.
Alabama	10	0	2	0	. .	. .	3	0	. .	. .	6	0
Minnesota	18	0	37	0	53	3	7	0	15	0	8	0
North Carolina	3	0	1	0	. .	. .	. .	. .	. .	. .	4	0
North Dakota	. .	. .	. .	. .	. .	. .	. .	. .	. .	. .	. .	. .
Virginia	4	0	2	0	. .	. .	. .	. .	. .	. .	6	1
Totals	35	0	42	0	53	3	10	0	15	0	21	1

Total number of different persons examined 183
" " " " passed 179
" " " " rejected 4
Total percentage of persons passed, .972 per cent.

TABLE III.

The following table indicates the result of the examination of 435 students, graduates of colleges formerly issuing degrees upon attendance of two courses of lectures:

State.	Univ. N. Y.		Jefferson.		Rush.		Bellevue.		Phys. and Surg., Baltimore.		Univ. Louisville.	
	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.	Passed.	Rejected.
Alabama	13	0	15	3	3	1	12	0	12	1	14	4
Minnesota	2	1	5	2	12	9	4	3	. .	. .	. .	. .
North Carolina	34	. .	39	2	. .	. .	17	3	69	25	3	4
North Dakota	. .	1	1	0	. .	. .	. .	. .	. .	. .	. .	. .
Virginia	14	6	20	8	0	. .	11	0	42	15	2	3
Totals	63	8	80	15	15	10	41	6	123	41	19	11

Total number of different persons examined 435
" " " " passed 343
" " " " rejected 92
Percentage passed, .788 per cent.
Difference in favor of Table II, .191 per cent.

colleges were selected, being those indicated by the report of the Illinois Board of Health as matriculating respectively the greatest number of students in the year 1890.

The above tables indicate that graduates of the three course graded colleges rarely fail before the various State Boards of Medical Examiners. Table No. 2 indicates 183 examinations with four failures; table No. 3, 435 examinations with 91 failures. The practice of medicine is fairly well regulated at the present time in about one-half of the States. The present indications are that the wave of reform will extend, and in the near future include all the States. The friends of medical legislation include the masses of the profession and the representatives of the better colleges of the country. Its enemies principally include the representatives of those colleges governed by commercial interests and charlatans.

Up to the present time the number of medical colleges has increased out of all proportion to the increase of population. Of 130 schools, less than a dozen are endowed. The number of practitioners is greatly in excess of the legitimate demands of the people. We are reliably informed that in a period of time ending with the decade of 1890, the colleges of the United States matriculated 115,355 students, and graduated 40,996. This is an average of 4,000 yearly; in my opinion more than twice as many as the requirements of the people demand.

As a final argument in behalf of adequate medical legislation, I beg to submit the following statistics, based upon the proportion of physicians to the number of inhabitants in a few of the European countries:

RATIO OF PHYSICIANS TO POPULATION.

Sweden	1 to 7,000	of population.
Italy	1 to 3,500	" "
Germany	1 to 3,000	" "
Austro-Hungary	1 to 2,400	" "
France	1 to 2,000	" "
United States	1 to 600	" "

The above figures explain themselves and comment seems unnecessary.

Basing my opinion upon observation of the workings of the Minnesota law in its last five years' experience, I am fully satisfied that efficient legislation will reduce the number of physicians to a number commensurate with the needs of the people, and the people themselves be better and more honestly served. Minnesota has a less number of physicians per capita than any State of the Union; St. Paul a less number than any of the larger cities of the United States. The result in this State is wholly due to efficient legislation, and the product of the act has been to enhance the welfare of both the profession and public.

Briefly, gentlemen, my conclusions upon the question of medical legislation can be summarized as follows, to wit: First, The regulation of medical practice and medical education is constitutional, and the demands therefore imperative. Secondly, That a distinct line of demarkation should exist between the so-called licensing power, and the regulation of medical education. Thirdly, That the licensing power should include in every State the following essentials:

a. That the evidence of the candidate's fitness to practice medicine should be established by his undergoing an examination upon all the important branches of medicine.

b. That there is absolutely no necessity for a series of questions that in the least conflict with the views of the various schools of practice.

c. That power should be granted to revoke or refuse license for unprofessional or dishonorable conduct.

d. That the exercise of this power upon the part of the different Boards should only be resorted to in palpably flagrant cases.

e. That the public interests will be best subserved by the so-called mixed Boards.

f. That the power vested is best executed by the State Sanitary Police, or rather, the different State Boards of Health.

g. The duties of the act belonging to that department of law known as the State Police Power, therefore the appointing power should be vested in the Governor.

h. Appointees should be men of recognized ability and standing in the various communities.

4. I am satisfied that the influences of efficient medical legislation will have a most salutary effect upon the character of the instruction afforded the students of medicine in this country, and that the faculties of the various colleges, in the future, will not be so notoriously lax in regard to the conferring of degrees.

5. It is likewise essential that medical education should be restricted or regulated in the various States, and that, in my opinion, there should be created a central authority consisting of a Bureau of Education, that this Bureau should have power to refuse or

revoke charters, and should exercise a restrictive influence as to the character of education, conferred, and that the authority should apply particularly to special schools of education, such as law and medicine.

6. That said Board should establish regulations pertaining to the granting of charters to medical colleges. The charters should not be granted unless all necessary laboratories were thoroughly equipped, that facilities for clinical instruction were unquestioned, and that applicants for charters should satisfy the Board of their undoubted ability to support the institution financially, without being dependent upon the fees of its students for its sustenance.

In a recent report of the Commissioner of Education of the United States, he forcibly directs the attention of the public to the very inadequate equipment of the medical colleges of this country. We are informed in this report that there are two million, six hundred and seventy-two thousand dollars invested in grounds, buildings and apparatus for the medical schools of the United States. The amount of productive funds for these schools is only two hundred sixty-six thousand, one hundred and ninety dollars, and the annual income from investments, only twenty-two thousand. He states "when we examine the facilities and demands of this country with those of the British Isles and Continental Europe, we necessarily conclude that the foreign schools exact too much, or that our system is painfully crude and lax." The Commissioner of Education further remarks, "that considering the enormous amount of knowledge that has been accumulated respecting the proper treatment of disease, its prevention, and its nature, the impression becomes irresistible that we have been influenced by our national impatience and haste in this matter, as well as in many others, and that we have allowed the student to dictate the length of time of study instead of obliging him to spend enough time to receive it properly and retain it securely. Applied to the profession of medicine there is but one inference to draw from the above data, we can only conclude that the facilities for securing a thorough medical education in this country are indeed inadequate. The present high character of the masses of the profession in the United States is not so much due to the facilities of college training, as to the individual character of the profession. The vast majority of the profession of this country, now in practice, received their degrees of M.D. after an attendance upon but two courses of medical instruction, of not more than twenty weeks duration each; many look back upon their medical college career as unimportant epochs, and think of those days as a work of confusion. The instruction afforded under this system of medical education was hurried, superficial and most inadequate to our wants. The course consisting rather in calling the attention of the student to the art of medicine, than to the teaching him of the sound principles upon which is governed the great field of active practice. This system of instruction was a delusion. Our experience confirms us in the opinion, that if the student does not become grounded in the essential principles of medicine in his college days, he never will. Except in a few rare instances a physician does not acquire histology, anatomy, physiology and chemistry, after receiving his degree of M.D. The few that have become proficient in later professional life have been placed at a very great disadvantage.

We are pleased to observe at this time a disposition to foster and support a higher system of education among the masses. The present disposition in the various States of the Union is towards a complete divorcement of the public school system from church or other influences, and affording to the public a system of education fully equal in quality, and as extensive in scope as can be obtained in any civilized country. This disposition is particularly noticeable in several of our Western States. We see here millions of dollars spent annually in the support of university education, and the facilities for instruction in several of these institutions are quite unsurpassed. We already have our University of Michigan, with its 2,800 students; the University of Minnesota, with its 1,300 students, and closely following, that of Wisconsin, Iowa; Texas and Nebraska.

The growing tendency of the State to foster higher education carries with it much encouragement for the profession of medicine. It means a medical department in connection with many of these institutions that are independent, and directly supported by the State. I am pleased to see a disposition in many of our colleges to connect themselves with universities. A medical college connected with a university has few objections and many advantages. As we pass the fourth centennial epoch in our history, we can look forward with most sanguine expectations in all that pertains to medicine. We invite our critics to forget the past and only look to the present and future. Present appearances plainly indicate that we are on the eve of a new departure in medical education in this country. The older system of medical education is a thing of the past; let us forget it quickly and look to the future.

In conclusion, I again appeal to the profession of this country, and particularly to you, gentlemen, the most intelligent representatives of the profession of medicine in America, to renew your zeal and continue in your efforts until the battle for higher medical education in America is actually won, and the good name of the profession of medicine rescued from disgrace.

The State Society of Arkansas elected the following officers at its late meeting: President, J. T. Jelks, Hot Springs; First Vice-President, A. C. Jordan, Pine Bluff; Second Vice-President, J. C. Wallis, Arkadelphia; Third Vice-President, J. W. Case, Batesville; Fourth Vice-President, G. D. Huddleston, Lamar; Secretary, L. P. Gibson, Little Rock; Assistant Secretary, W. B. Lawrence, Batesville; Treasurer. A. L. Breysacher, Little Rock; Librarian, R. B. Christian, Little Rock.

Tri-State Medical Society of Alabama, Georgia and Tennessee will hold its fourth annual session in Chattanooga, Tenn., October 25, 26 and 27, 1892. The membership is not strictly limited to the profession from the States named in the title of the Society, but men of eminence from other States may be elected. Under the vigorous management of its present corps of officers, it is needless to assure our readers that the coming session will be a great success. The mention of the names of Dr. W. E. B. Davis, of Rome, Ga., as President; Drs. D. H. Howell, J. C. Shepard, and J. P. Stewart, as Vice-Presidents; Dr. Frank Trester Smith, of Chattanooga, as Secretary; Dr. W. L. Gahagan, of Chattanooga, Tenn., as Recorder, etc., give sureties of active work and successful results. Papers for the session are already promised by the president, by Drs. I. N. Love, of St. Louis; J. W. Cowan, of Tullahoma, Tenn.; E. B. Ward, of Selma, Ala.; J. M. Head, of Zebulon, Ga.; John L. Howell, and J. N. Masters, of Knoxville, and C. S. Briggs and Richard Douglas, of Nashville.

LAST ONE HUNDRED ABDOMINAL SECTIONS FOR REMOVAL OF OVARIAN TUMOR AND DISEASED UTERINE APPENDAGES.

BY R. STANSBURY SUTTON, M.D., PITTSBURGH, PA.

Medical Attendant.	Patient.	Age.	Ovariotomy. Double or Single	Removal of Appendages. Double or Single	Weight of Tumor.	Descriptive Remarks.	Date.	Place of Operation.	Result.
Drs. Robertson and Floyd	Miss R.	27		Double		Chronic salpingitis and ovaritis. Adhesions. Tate knot	April 26, '87	Private hospital	Recov'd.
Dr. Williamson	Mrs. D.	36	Double		12 lbs.	Multilocular cyst of right ovary. Pedicle tied and burnt. Left ovary cystic	Nov. 5, '87	“ “	“
Dr. Phillips	Mrs. M	27	Single		30 “	Parovarian cyst. Forty square inches anterior abdominal adhesion	Nov. 9, '87	“ “	“
Dr. Floyd	Miss S.	31		Single		Left chronic ovaritis and salpingitis. Right ovary removed one year previous	Nov. 17, '87	“ “	“
Dr. Boal	Mrs. B.	31	Double		20 lbs.	Multilocular dermoid cyst. Second ovary cystic. Pedicles tied and burnt	Mar. 21, '88	“ “	“
Dr. Sykes	Miss W	32	“		30 “	Non-adherent cyst. Second ovary cystic. Patient very feeble	May 10, '88.	“ “	“
Dr. McDonnald	Mrs. H.	27	Single		25 “	Non-adherent cyst. Pedicle tied and burnt	Oct. 11, '88.	“ “	“
Dr. Ross	Mrs. S.	17		Double		Prolapsed ovaries; pelvic pain; mental aberration. Last cured by operation	Oct. 30, '88	“ “	“
Dr. McDonnald	Mrs. L.	35		“		Unbearable dysmenorrhœa. Ovaries and tubes buried in adhesions. Abdomen very fat	Nov. 3, '88	“ “	“
Dr. Stewart	Mrs. H	20		Single		Left chronic ovaritis and salpingitis	Nov. 7, '88	“ “	“
Dr. Purington	Mrs. S.	58	Single		30 lbs.	Ruptured multilocular cyst. No adhesions. Drainage	“	“ “	“
Dr. Williamson	Mrs. McC.	21		Double		Married two years; sterile; [illegible] convulsions. Salpingitis	'88.	“ “	“
Dr Rough	Mrs. R.	33		“		Sterile; had had pelvic ab- [illegible] had been recommended by me, five years previous, when single	Dec. 1, '88.	“ “	“
Drs. Porter and Fish	Mrs. H.	26		“		In bed greater part of time for five years. Pelvic abscess one year before	Dec. 3, '88.	“ “	“
Dr. Williamson	Miss P.	23	Single			Imperforate vagina; infantile, unicornuated uterus. Normal ovary and tube on right side. None on left	Dec. 11, '88.	“ “	“
Dr. Bell	Mrs. B.	46	“		8 lbs.	Cysts on both sides; left pediculated. Right malignant	Feb. 18, '89.	“ “	“
Dr. Sloan	Mrs. G.	50	“		25 “	Multilocular cyst. Pedicle tied and burnt	Feb. 19, '89.	“ “	“
Dr. Hunter	Mrs. A.	24	“		5 “	Tumor. Extensive adhesions	April 7, '89.	“ “	“
Dr. Stewart	Mrs. H	21		Single		Right ovaritis and salpingitis; 2nd operation	“ 15, '89.	“ “	“
Dr. Klingensmith	Mrs. L.	23		Double		Had had pelvic abscess, pelvic peritonitis, menorrhagia. Ovaries and tubes adherent.	“ 27, '89.	“ “	“
Dr. Williamson	Mrs. H.	25	Double		10 lbs	Parovarian cyst. Second ovary cystic	May 7, '89.	“ “	“
Dr. Clark	Miss S.	27		Double		Ovaritis and salpingitis. Pedicle tied and burnt. Drainage	“ 9, '89.	“ “	“
Dr. O'Brien	Mrs. B.	29		“		Gonorrhœal salpingitis	June 12, '89	“ “	“
Dr. Sutton	Mrs. A.	30		“		Long, persistent pelvic pain. Pain cured, but cause undetermined	“ 22, '89	“ “	“
Dr. Robinson	Mrs. M.	29		“		Uterine hæmorrhages and great pelvic pain. Ovaries and tubes adherent. Not cured	July 8, '89.	“ “	“
Dr. Simpson	Mrs. W	28		“		Sterile; ovaries cystic; chronic salpingitis	Sept. 10, '89	“ “	“
Dr. McCard	Mrs. A.	41		“		Bleeding fibroid. Subsequent reduction in size of tumor	Oct. 6, '89.	“ “	“
Dr. Ackerman	Mrs. L.	29		“		Pyosalpinx	“ 19, '89.	“ “	“
Dr. Patton	Mrs. S.	28	Single		15 lbs.	Multilocular ovarian cyst. Ligatured	Nov. 2, '89.	“ “	“
Dr. Williamson	Miss B.	36		Double		Bleeding fibroid. Two hæmostatic forceps left on deep pelvic vessels for 24 hours	“ 28, '89.	“ “	“
Dr. Green	Mrs. M	42	Single			[illegible] ent dermoid; died of shock	Dec. 19, '89.	“ “	Died.
Dr. Waples	Mrs. C.	56	“				“ 23, '89.	“ “	Recov'd.
Dr. O'Brien	Mrs. S.	34	“		20 lbs.	Cyst	Feb. 3, '90.	“ “	“
Dr. Williamson	Miss T.	22		Double		Patient insane; confined in straight-jacket; ovaritis and salpingitis; insanity cured	“ 12, '90.	“ “	“
Dr. Knox	Mrs. S.	37		“		Old pelvic inflammation; appendages adherent to omentum and intestines; drainage	“ 25, '90.	“ “	“
Dr. Storer	Miss H	21		“		Severe hæmorrhages; interstitial fibroid	“ 27, '90.	“ “	“
Dr. Dean	Miss C.	30	Double			Dermoid size of orange, encapsulated by adhesions to omentum, intestines, uterus, tubes and pelvic floor; drainage	Mar. 5, '90.	“ “	Died.
Dr. Pershing	Mrs. B.	41		Double		Old invalid; ovaries and tubes completely embedded in adhesions; drainage; cured.	“ 10, '90.	“ “	Recov'd.
Dr. Blaby	Miss L.	15	Single		35 lbs.	Multilocular cyst; pedicle tied and burnt	“ 22, '90.	“ “	
Dr. Benham	Mrs. B.	51	“		40 “	Fibro-cystic tumor of right ovary; extensive adhesions	“ 23, '90.	“ “	“
Dr. Johnston	Miss McD.	44		Double		Chronic salpingitis and ovaritis	April 9, '90.	“ “	“
Dr. Walker	Mrs. O'T	27		“		Ovaritis, salpingitis and pelvic peritonitis	“ 21, '90.	Home	“
Dr. Stewart	Mrs. H.	60	Single		50 lbs.	Suppurating multilocular cyst; frequently tapped; had phlegmasia dolens	May 3, '90.	Private hospital	“
Dr. Tressel	Mrs. H.	30		Double		Salpingitis and ovaritis	“ 29, '90.	“ “	“
Dr. Klingensmith	Mrs. K.	53	Single			Unilocular cyst; extensive adhesions; stitched incision; drainage; cured	June 2, '90.	“ “	“
Dr. McCready	Mrs. G.	23		Double		Bleeding fibroid; ovaries and tubes diseased	“ 7, '90.	“ “	“
Dr. Sutton	Mrs. S.	43		“		Multiple fibroids	“ 10, '90	“ “	“
Dr. Laidley	Mrs. R.	46		“		Uterine hæmorrhages; interstitial endometritis	“ 12, '90.	“ “	“
Dr. Bell	Mrs. M.	30		“		Chronic neurasthenic invalid; interstitial salpingitis; cured	“ 18, '90.	“ “	“
Dr. Bell	Miss W	22		“		Round ligaments shortened by Dr. Gill Wylie one year prior. N. G. Chronic salpingitis	“ 19, '90.	“ “	“
Dr. Sharpneck	Mrs. B.	46	Single		71 lbs.	Multilocular cyst; Brown's clamp and cautery; drainage	Sept. 4, '90.	“ “	“
Dr. Pollock	Mrs. D.	58	“			Multilocular dermoid cyst	“ 6, '90	“ “	“
Dr. Kirker	Mrs. T.	65	Double			Cancer of both ovaries and omentum; all removed	“ 9, '90.	Home	“
Dr. Banks	Mrs. L.	48	Single		18 lbs.	Parovarian cyst; Brown's clamp and cautery	Oct. 22, '90.	Private hospital	“

SYNOPSIS.

In these one hundred cases, which I have the pleasure to report to you, there were:

Fifty-four abdominal sections for removal of diseased appendages with one death, which was caused by suppurating pelvic peritonitis.

Forty-six abdominal sections for removal of ovaries, the seat of tumor, with six deaths, which were cause as follows:

The first, Mrs. M., had been confined a short time previous; was thoroughly septic, having chills, sweats and irregular temperature, pulse ranging from 120 to 130, prior to operation. Died of shock 48 hours after operation.

Second, Mrs. C., the operation was extremely difficult. An intestine was injured, hæmorrhage was profuse, operation was prolonged and vomiting after anæsthesia was uncontrollable. Died from shock 48 hours after operation.

Third, Mrs. K., operated under protest made to her physician and husband together. The operation was completed in a few minutes with moderate loss of blood, and as I predicted, patient died on the table, ten or fifteen minutes after the operation had been completed. There was plenty of time to have her removed from the table, but I refused to have her moved. Her profound neurasthenia was the cause of my protest. Died of shock.

Fourth, Miss K., was operated with phthisis pulmonalis, a sequela of la grippe. Tumor was large.

She should have been tapped and not operated. Died from exhaustion, the result of colliquitive sweats and persistent cough.

Fifth, Mrs. J., a woman 62 years old with cancer of both ovaries, enormously distended with fluid and very much exhausted. I protested against operating. The protest was made to her husband and physician a second time before she was anæsthetized; my judgment was overruled and my prediction that she would die verified.

Sixth, and last case, Mrs. G., operated without difficulty or unusual incident. On sixth day had stercoraceous vomiting with great tympany. I button-holed the ileum in left inguinal region. Distention was relieved and vomiting ceased. Died on 14th day. Post-mortem showed no cause of death attributable to the ovariotomy. No fluid in abdominal cavity. Lower three feet of ileum and entire colon were gangrenous. Died of thrombosis of nutritive vessels. Thrombi were derived from varix as large as an egg situated in scarpal triangle and connected with femoral vein.

Five of these deaths in the forty-six ovariotomies could have been avoided by refusing the cases, which would have been the proper thing to have done. In the future I shall certainly act upon my own convictions, without reference to what becomes of the case afterwards; a position, however, which perhaps only an experienced operator has the right to assume, for all know how frequently the most unpromising cases will survive operation.

PREPARATORY TREATMENT.

The preparatory treatment of these patients, has been about as follows:

The patient is put to bed 48 hours prior to operation, her bowels thoroughly emptied and during the second 24 hours, her diet is limited to nutritious soup, bread and tea. She has had at least two baths at which the cilia about the genitals have been thoroughly cleansed and the vagina washed out with hot water. One hour before operation, a towel wrung out of a hot 1:1,000 sublimate solution is laid over the abdomen and removed on the operating table.

TECHNIQUE.

At the operation besides the anæsthetizer, one assistant and two nurses are used. One nurse has charge of sponges, the other instruments, needles and ligature.

The first stage of the operation, viz: Opening the cavity of the abdomen, varies from five to fifteen seconds. The incision is made in the median line.

The second stage of the operation, adhesions being present or absent, if the case is one of cystic tumor varies from one minute to ten. The average being four and one half minutes. If the appendages are to be removed adherent or non adherent, the time for both sides varies from four to twelve minutes; the average being probably between eight and nine minutes.

The third stages of the operation, the "Toilette de Pentonine" depends largely on whether there are vessels to take up, fluids to wash out or drainage to be applied. The time varies from seven to twenty-eight minutes. The average being probably very close to thirteen minutes. This includes, of course, suturing the abdominal wound.

After the wound has been sutured it is covered with a layer of aristol; this with eight thicknesses of aseptic gauze; this with a thin layer of aseptic cotton, and all this secured by a scultetus bandage.

Neither in the sponges nor in the water covering the instruments and suture, is any chemical introduced. If it is necessary to flush the abdomen it is done with simple boiled tap water.

AFTER TREATMENT.

The after treatment is of the simplest character. During the first 38 hours the patient gets nothing except sips of hot water, and is encouraged to take as little of this as possible. If she suffers from thirst, occasionally four ounces of warm water are thrown into the rectum. Between the 38th and 48th hour she is allowed to take toast water and tea unless her stomach be irritable, in which event she is given a Seidlitz powder,or ʒj Rochelle salts, or a two grain pellet of cloral; the latter if the tongue be furred. At the end of 48 hours, nutritous soups and bread crumbs initiate a more liberal diet a few days later. In very feeble patients, nutritive enemata of peptonized milk are given from the end of the first 24 hours. When it has been necessary to leave the drainage tube in the lower end of the wound, the tube is emptied, and the super dressing changed every two hours until the end of the sixth hour; then every four hours until the end of the first 24 hours and every eight hours from that until the time of its removal, should it be continued beyond 24 hours. If the wound has been aseptic and the vitality of the tissues sufficiently good, no suppuration occurs. If however, this fortunate condition does not exist, about 17 hours after operation the temperature will usually reach a fraction above 100° F., and for the first two or three days will fluctuate between $99\frac{4}{5}$ and 101. Under such circumstances a twenty grain suppository of quinine is given every 24 hours. The wound is examined daily,any offending stitches removed, and usually the result in pus formation is insignificant. It occasionally occurs in a very fat abdomen or in that of a patient extremely debilitated,both conditions predisposing to low vitality,that suppuration will occur to a considerable degree. Early evacuation of the pus, thorough cleansing of the pus cavity or sinus with hydrogen peroxide and subsequent stimulation of its walls with iodized water, with or without the introduction of a small rubber drainage tube, has been followed uniformly by the speedy recovery of the patient.

The average time for laparotomy patients from date of operation is 16 days and the average time in the private hospital is about 23 days.

Increased experience in operating and through this an acquired ability to discriminate justly against hopeless cases as already proven in this table, will, I am confident, enable me to reduce my mortality in the next hundred similar cases to less than seven per cent. Had I maintained my convictions with reference to two of the cases in this table the mortality in the last hundred cases done at this writing would have been but five per cent., and experience has taught me that if a woman who is the subject of phthisis pulmonalis has an ovarian cyst, that it is wise to be contented with tapping. Had this lesson been learned earlier the mortality in this table would have been but 4 per cent. With these considerations I feel confident that the efforts of the future will be better.

SOCIETY PROCEEDINGS.

American Otological Society.

Twenty-fifth Annual Meeting, held at the Fort Griswold House, New London, Conn., July 19, 1892.

The Society was called to order by the President, Dr. Gorham Bacon, of New York. The first paper was by Oren D. Pomeroy, M.D., New York, entitled:

CASES OF MASTOID DISEASE EXHIBITING SOMEWHAT EXTENSIVE CARIOUS PROCESSES.

Case 1.—J. W., æt. 19 years, applied November 22, 1887. In December, 1885, he had a post-aural abscess, which was incised. A few months afterward, the mastoid was freely opened and carious bone removed. On entering the hospital the mastoid opening was nearly closed, and the middle ear was suppurating. There was a swelling below the auricle, red and painful, and preventing free movement of the jaw. Pressure on this part evacuated pus from the tympanum.

November 24, the swelling has extended to the face. Temperature 101.4°, pulse rapid and weak. Nourishment and stimulants used. The patient was etherized, and the granulations in the tympanum were removed by the curette. The opening in the mastoid was extended downwards and opened into a large cavity that seemed to include the mastoid and tympanum. A large quantity of pus was evacuated by syringing. Temperature in the evening 103.6°.

November 25, temperature 99°. Within two days an abscess in front of the velum on the left side was opened. This showed no apparent communication with the ear cavity. During the next three days the temperature was nearly normal, and after this became so. Antiseptic irrigation was continued. After two weeks, the discharge became much less and the carious cavity showed signs of filling up with healthy tissue. The abscess in the throat was probably due to the ear trouble.

Case 2.—M. G., æt. 34 years, admitted February 29, 1890. In December last had acute suppurative otitis in left ear, with mastoid periostitis. Wilde's incision was done. On entering the hospital there was an opening in the mastoid three-quarters of an inch deep, into which the little finger could be thrust, at the bottom of which pulsation was apparently felt. The meatus was filled with dried epithelium and pus. There was elevation of temperature from rheumatism in the left hip-joint. The mastoid cavity was cleaned out and packed with iodoform gauze. Large doses of iodide of potassium were given. Temperature a little elevated in the evening. March 4, easily detachable bits of carious bone were removed with curette and gouge. Temp. 103°, but this was reduced by phenacetine. By March 20, temp. became normal. Stimulants were freely used and the patient became much better, and was able to walk about the wards.

April 7, pieces of carious bone were removed by the bone curette and gouge. Other portions were washed out by the syringe. Considerable granulation material and a cheesy substance were also removed. The part was dressed with iodoform gauze after irrigation with bichloride solution. The patient was discharged April 21, much improved.

Case 3.—T. S., æt. 16 years, came into the hospital August 11, 1891, with an acute suppurative otitis media of both ears. Six days later a Wilde's incision was done on the left mastoid. The discharge continued from each ear when he left the hospital some weeks later.

March 23, 1892, he came under the author's care for the first time. Over the left mastoid was a small aperture leading into a large carious cavity which included the mastoid and tympanum. This opening was enlarged by a stout knife so that the finger could be introduced into the mastoid cavity. Dead bone and granulations were found. On syringing a soft flocculent material, resembling broken down brain substance, was removed in large quantities. Granulations were removed from the drum cavity by the curette. The opening in the mastoid was more than an inch in depth. Antiseptic irrigation was practiced, and cotton smeared with vaseline 5,000 parts and bichloride one part, was applied to the wound. After three weeks, granulations and small bits of bone were removed by the curette. On May 10 an abscess appeared above the meatus and communicating with it. This was opened and found not to communicate with dead bone. It was treated antiseptically and by a compress. June 20, 1892, the mastoid is closed and the discharge from the ear has nearly ceased. He hears words loudly spoken close to the ear.

The right ear in the meantime has filled with granulations which were removed with the curette. On April 8, it was found that pressure on the mastoid caused pus to exude from the meatus and a Wilde's incision was done expecting to find an opening in the mastoid, but none was found. The wound was kept open by a cotton tent. May 9, there was an opening into the mastoid and two or three considerable masses of dead bone were drawn out with artery forceps. This left an enormous cavity which seemed to include the tympanum. Polypi were also removed. There was much hæmorrhage. Antiseptic irrigation was practiced, and vaseline and bichloride on cotton was applied. Since this time granulations and bits of bone have been removed. June 20, 1892, the external wound has closed with considerable sinking and the ear has almost ceased discharging. The temperature has some of the time been above normal and seemed as though recovery would be impossible.

Case 4.—A. W., æt 2 years, has suppurative otitis of the left ear dating back five months. The author first saw her November 1890; when the tympanum was full of polypi. There was a large carious opening in the mastoid which was filled with granulation. Small bits of carious bone and cheesy looking detritus were removed. These were removed and the wound irrigated and dressed with bichloride gauze. Patient was much improved in a few days. After another month more granulations were removed and some dead bone. Four months later, the mastoid opening was closed with considerable sinking. The discharge from the ear diminished after each operation.

Case 5.—J. S., æt. four months had a swelling behind the left ear of four days' duration with a discharge from the ear for one month. A Wilde's incision was made and an opening into the antrum found. There was considerable discharge of pus. Antiseptic irrigation and bichloride gauze dressing. After a few days a probe was passed in one and one-half inches in the direction of the tympanum touching bone. This opening was enlarged by the drill and kept clear by syringing with an antiseptic solution. The patient was brought very irregularly and the treatment was not carried out intelligently and the child died two months later with brain symptoms.

Case 6.—A. P., Italian; æt. 42 years; has an otitis media suppurating since three months with a swelling over the mastoid. The latter was at once incised, and a handle of a scalpel could be thrust through an opening in the cells which seemed to include the tympanum in its area. Antiseptic irrigation was practiced for some weeks. March 22, the temperature was 100.2°. Granulations were removed from the mastoid. On the 23d, there was considerable œdematous swelling about the mastoid which subsided in a few days and the temperature became normal. On March 29, some pain in the side of the head was relieved by quinine. A subsequent headache was relieved by bromidia. More granulations and dead bone were removed. April 18, temperature 100.5° with headache. The next day was better. Being offended he made a serious attack on the nurse. He was then sent to the N. Y. Insane Asylum to be examined as to his mental condition. He was however, soon discharged from the asylum. The patient has recently been heard from and the ear symptoms are not urgent.

Case 7.—A. P., æt 42 years; has a suppurative otitis media on the left side of one week's duration, and a painful swelling over the mastoid since two weeks. Pus was evacuated by a Wilde's incision. A large opening was found in the mastoid extending inward one and one-quarter inches from the skin surface. It was streated by antiseptic irrigation using a hard rubber drainage tube. After four weeks of treatment the external wound was nearly closed but the temperature was 99.6, and a sequestrum of bone was found. There was also apparently some cellulitis of adjoining soft parts, the opening was enlarged and more dead bone removed. After this there was decided improvement and the patient disappeared from observation.

In reviewing these cases it will be seen that no effort was made to remove all the dead bone, but whatever was loose or readily detachable was taken away. Adequate antiseptic drainage was carefully looked after and the vital energies were kept up by stimulants, tonics, food and proper nursing.

(To be concluded.)

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
NO. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. *All that is necessary is for the applicant to write to the Treasurer of the* Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, JULY 30, 1892.

THE HOT SEASON AND CONSEQUENT AILMENTS.

During the last few days an atmospheric wave of unusual high temperature has passed from West to East over the Northern States, Fahrenheit thermometers marking over 90° for nearly the entire day for more than a week. This is dangerous weather and carries with it a death mark to many houses. The daily press tells of the adults who directly succumb to the effects of the heat, but leaves unrecorded the names of scores and hundreds of invalids and infants whose lives go out as they wilt before the Sirocco. While the immediate mortality has been appalling, the enervating and debilitating influence of the heat will for weeks and months continue its depressing influence.

From this heat will be dated the beginning of innumerable cases of summer complaint, diarrhœa, dysentery, nervous prostration, and mental aberration. The mortality and suffering from these affections may be greatly lessened by timely advice from family physicians.

The knowledge should be made common among the people, that for heat stroke or prostration, the patient whether old or young, should be immediately removed, if in the sun, to a cool and shaded place, the clothing loosened and much of it taken off, and when possible, plunged in a cool bath, or showered with cold water from a sprinkling can; care being taken to remove the patient from the bath, or to stop the sprinkler before the temperature has reached the normal, lest collapse ensue.

Frequent and free baths in cool water cannot be too strongly urged, particularly upon the large population in city tenement houses. These people do not have bath room facilities and accommodations, but they do have ordinary washtubs that answer an admirable purpose as a plunge for the little ones, and a sponge off and ablution for those who are older.

This is trite and elementary information to our readers, but is gone over in order to direct attention to a prophylactic measure that should be urged upon the poor, and particularly upon those who swelter in sweat shops, and similar places.

* * * * *

The prevalence and continuance of summer complaint is in direct proportion to the height of atmospheric temperature, and for this the very best remedies are of the prophylactic order, and of these the knowledge should be made common among the people, and particularly among the poor. In addition to the bathing referred to, a suitable diet and resort to the parks, lake, river, or seaside are absolutely essential for the preservation of much of the child life of the great cities.

For nursing infants, the mother's milk is the best diet in most cases, but not infrequently this is an irritable or indigestible food for the child, and is often supplied in insufficient quantity. A wet nurse is an excellent substitute, but for one reason or another, in a vast majority of instances is not available. The diet that is most convenient and frequently resorted to, is cow's milk. For infant or invalid feeding this should be sterilized as quickly as possible. This may be done by pouring the fresh new milk into a perfectly clean bottle, lightly stoppered with a clean new cork, then place the bottle in a pan or other vessel of warm water, which should be heated to the boiling point and kept there for not less than twenty minutes. A few grains of table salt should be added to the milk. The bottle may now be closely stoppered and set in a cool place.

Milk sterilized in this manner is palatable and wholesome for several hours, or even for a whole day. This simple and inexpensive process can be carried out in any family.

Milk is like a sponge in its power of absorption, taking up the contaminating properties of the surrounding atmosphere with the greatest rapidity; for this reason mothers and housewives should know that its use should depend upon their most careful and immediate attention.

* * * * *

Don't always think that because a mother is an educated woman that she consequently knows enough to frequently give the baby a little drink of cool water. A little at a time and often should be the rule. Many mothers don't know this, but as a substitute place the puling infant at the breast to stop its crying.

All cases that are severe enough to have medication should be under the direction of a physician.

DR. SAMUEL S. ADAMS has accepted the Professorship of Clinical Pediatrics in the Medical Department of Columbian University, Washington, D. C., having resigned from the chair of Theory and Practice of Medicine in the National University of Washington City.

THE FUNCTIONS OF THE STOMACH AFTER GASTROSTOMY.

EWALD has observed the functions of a stomach which has been subjected to gastrostomy, and reports some of his findings in the *Deutsche Medizinal-Zeitung* for March 24. In this case the peptic activity of the stomach was entirely destroyed, and the nutrition began to take place in the intestines. The movements of the stomach were lessened, and a certain amount of stagnation of the gastric contents took place in consequence of adhesions. For this reason EWALD has suggested that the fistula should be made near the pylorus, so that the food, or some of it, can be introduced by a tube directly into the duodenum. So long as a patient's strength is maintained gastrostomy cannot be strongly recommended. The prognosis of obstruction due to pressure from without is much the same as that due to tumor unless the tumor is syphilitic. The stricture may be due to peptic ulcer in the lower part of the œsophagus; this lesion is due to corrosion by the gastric juice and occurs in anæmic subjects. The age is very important. Unlike carcinoma, attacks of pain are noted and obstruction later. The patient upon whom EWALD made his observations was a female, aged twenty, who had previously suffered from gastric symptoms and then had had an interval of health lasting a few months. About one year ago, pain began again, followed by difficulty of swallowing. The bougie could not be passed. There was wasting; no history of syphilis. A gastrostomy was done by OPPENHEIM, the opening into the stomach being made at the end of five days. The patient gained rapidly in weight, but the constriction did not relax sufficiently to permit of the passage of a bougie. The fact of dilatation of the stomach, with delayed passage of food, favored the diagnosis of cicatrized ulcer near the pylorus as well as in the œsophagus. Through a speculum the cardiac end of the organ appeared too red, and the pyloric too pale. The sound could be passed five inches upward and six inches downward, but it could not be made to pass into the gullet or duodenum. The pressure in the moderately filled organ was expressed by EWALD at from 30 to 35 millimetres, and with moderate external compression at from 80 to 100 millimetres. This pressure was increased by applying the faradic current to the abdominal wall, but not by applying the current to the inside of the stomach. This was due to adhesions. Salol excretion was delayed, salicylic acid appearing in the urine two and a half hours after food, owing to stomach dilatation. If the stomach were washed out the night before, a fluid containg free hydrochloric acid and with peptic properties could be obtained on the morning following. The patient survived the operation five months.

DANGERS FROM A MISUSE OF STOMACH-WASHING.

In a recent number of the London *Practitioner*, DR. SOLTAN FENWICK has described some of the objectionable features of lavage, when indiscriminately practiced. In his view of the case, this comparatively new measure has been used more frequently than is just and proper. Not only have chlorosis, atonic dyspepsia and the gastric crises of locomotor ataxia been thus treated, but also not a few cases where the vomiting was of purely reflex origin. Twenty-five cases of convulsions in chronic gastric disease, have been studied by the author. In six of these the attack was apparently due to the stomach-tube. Other irritative causes than mechanical ones may, as is well-known, result in both general convulsions and in tetany, when the gastro-intestinal track is in question, but in several cases observed by the author it was manifest that the stomach-tube was the prime factor of the disturbance. Tetany, from gastric irritation, has been described as a very fatal complication, upwards of sixty per cent. ending in death. Another kind of untoward result, namely the perforation of the wall of the stomach, at a point already thinned by a gastric ulcer, by the pressure of the stomach-tube, has been known to end in a fatal peritonitis. Hæmorrhages have not infrequently followed the use of the stomach-pump, in cases where carcinomatous or ulcerative disease was present.

Three cases of poisoning by boric acid have been found by DR. FENWICK, due to the employment of solutions of that acid as an antiseptic in cases of gastric disease. Two of these cases ended fatally. It is probable, in regard to these cases, that the irrigation of the stomach was carried out in an imperfect or careless manner, so that an unduly large quantity of the acid remained, after the tube was removed.

These "accidents" by no means impeach the use of lavage in the proper range of cases, but they teach the imperative need of watchfulness and judgment in the choice of cases that shall be treated by that method. It will become obvious to others, as it has to DR. FENWICK, that cases not benefited are apt to be made worse, since as LEUBE has pointed out, the tube removes more or less of those products of digestion whose manufacture by the stomach has caused that organ not a little labor. It is not probable that the washing out of the organ, in a case where the digestive secretion is below the normal, will add to or improve its physiological powers. And we cannot justly expect that this procedure can prevent the recurrence of conditions and symptoms which are an indirect result of an organic disease in another viscus outside the stomach. He tried lavage in one case of tabes, marked by severe gastric crises, using it daily for several weeks, but without any good influence over the digestion. In a few cases of anæmia and dyspepsia, failure also resulted in his use of lavage; but these persons, or some of them, began to improve under some of the older and more ordinary lines of treatment. In conclusion he holds that lavage cannot be employed successfully unless employed indiscriminately; that its loose use is liable to prove a curse rather than a benefit, and that not only will some of the patients be made to suffer, but the method itself may be brought into disrepute among those for whom it might satisfactorily be used.

THERMIC FEVER.

A large proportion of cases of this affection are speedily fatal. Those who do not immediately succumb are apt to suffer from a lesion of the nerve centers, for which complete rest in a cool climate, and freedom from mental labor, irritation, exertion and anxiety should be enjoined. Simple tonics, nutrients, salt baths, and laxative waters with hygienic surroundings are indicated. Notwithstanding the patients being placed under the most favorable conditions indicated, very many fail to recover, lose their mental equilibrium, become dead to the world and end their lives as inmates of sanitariums and asylums.

THE AMERICAN SOCIETY OF MICROSCOPISTS.

This Association of scientists will meet at Rochester, N. Y., August 9, 10, 11 and 12.

The volume of proceedings of last year's meeting is exceedingly rich in the character of its contents, and is particularly valuable to physicians. We are pleased to note that a large proportion of the members are medical men.

For the consideration of the American Society of Microscopists we suggest that they hold their annual meetings during the week preceding or following that of the American Medical Association, and at the same place. A Section on Microscopy will no doubt be created in the latter organization, so that a unification of time and place of meeting will be of great advantage to the scientists who are engaged in this fascinating and profitable line of work.

INCOMPATIBLE WITH ANTIPYRINE.—The salicylate of sodium and antipyrine form a mixture from which an oily substance separates. The same is true of chloral hydrate. With beta-naphthol, antipyrine becomes hygroscopic. These changes take place when dry trituration of the respective substances is undertaken.

THE quotation, "Who shall decide when doctors disagree and soundest casuists doubt like you and me," was written by *Alexander Pope, Moral Essays, Epistle 3, line 1.* The original did not apply to doctors of medicine, but to doctors of philosophy. Yours, J. B. H.

ERRATA.—In our last issue, in the book review of McClellan's Anatomy, the name of the first descriptive anatomist was misspelled, it should be Alcmeon.

DOMESTIC CORRESPONDENCE.

"The New York Medical Journal And The American Medical Association."

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

In the ASSOCIATION JOURNAL for July 23, 1892, is a letter from J. F. Jenkins, M.D., having the above caption, in which exception is taken to an editorial on "The American Medical Association" that appeared in the *New York Medical Journal* for July 16. The writer has misinterpreted the spirit of the editorial, apparently basing his misinterpretations on the ground that the editor of the *New York Medical Journal* is not a member of the American Medical Association. While this latter fact is true, it is also true that he takes a lively interest in the welfare of the Association and would gladly see it attain the commanding position that should be its province. But the writer overlooks the fact that in the journal referred to, as in all medical journals, the editor does not write all the editorials. And the member of the editorial staff who wrote the editorial is almost as old a member of the Association as is Dr. Jenkins, and is one who has done whatever was in his power, both as a member and officer of the American Medical Association, to further its interests.

A fair acquaintance with members of the profession in various sections of the United States suggests a classification of the members of the regular profession into, first, those who are indifferent to the Association; second, those who—like the Laodiceans—are neither warm nor cold; and third, those who are favorable towards it. This classification has been arranged in the order of numerical proportion, and it may be verified by referring to the printed list of members of the Association in THE JOURNAL for December 26, 1891, and some register of the physicians of the United States. That class of professional men to whom Dr. Jenkins refers as desiring the destruction of the Association, has not been met with anywhere; it seems as if Dr. Jenkins had echoed an assertion that has been made before, but made on the ground of heated and intemperate expression that ignores the right, not only of a just difference of opinion, but of the privilege of comparing facts regarding various scientific organizations.

An error has unwittingly crept in in Dr. Jenkins' second paragraph. The report of the committee on page 798 of Vol. xviii, of the Association Journal, is not on the Section of Dermatology alone, but on all the Sections, and to all the just criticism of that committee applies. And in order to remedy the deplorable condition of affairs a radical change has been made in the By-Laws governing the Sections.

If Dr. Jenkins will look over the list of members who have attended the last few annual meetings, then look at a list of the members of the Association, and then refer to a list of the members for 1884, say, he will appreciate the justice of the criticism. Let him think over the representative names in American medicine; the men who speak as having authority; the men who have attained their prominence by work in the hospitals and in practice, and not by professional log-rolling! Has the American Medical Association had the majority, or even one-half, or even a smaller proportion of these men in attendance? When thinking of the prominent men who do come, it almost seems as if the Association were under a special obligation to them for their efforts and the lending of their prestige to the Association.

The question of patriotism might arise in a comparison of American and foreign institutions in general; but in science all lands, one's country, and all countries, home, and it savors of evasion to introduce patriotism into a question of facts. Comparison was made with the British Medical Association because its organization is more like our own, and because its journal was easily accessible to institute the comparison suggested if the reader so desired. It is not necessary to attend the English meetings to ascertain the verity of the statement; simply judge by the papers read before each organization. The report of the committee referred to in the first portion of this communication would substantiate the writer's position by itself. But if further evidence is desired, the writer's own experience, during two years that he held office in the Association, in the almost fruitless effort to enlist the coöperation of the best known men in the special work he was engaged in would serve as a basis for all that he said.

The editorial was written, as its tenor purports, to assure the Committee on the Revision of the Code of Ethics that if they would report a recommendation to abolish the entire Code as one of the fundamental features of the Association, their work would be warmly appreciated. It is a firm belief of the writer's that it has not made one man a better man or physician; for, in the language of the Orient, "You can water, fertilize and cultivate a field of thistles for a lifetime and the fruit remains the same, and you can leave a date palm to itself and it will always produce dates;" or in the homely proverb of the Anglo-Saxon, "You cannot make a silk purse out of a sow's ear." The physician who is a gentleman will be one whether the Code exists or no, and the reverse is equally true. Personally, most of the references I have ever seen made to the Code of Ethics have been for the purpose of satisfaction for some fancied wrong, and not from a desire to uphold the dignity and purity of the medical profession.

The existence of the Code savors of Pharisaism, and wrapping its mantle of holiness about us, we are tempted to be more impressed with our own virtue than with the scientific demands of the work upon which we are engaged. We have the example of many organizations before us; and a simple by-law to the effect that any member may be expelled for conduct unbecoming a physician and a gentleman, would eliminate what has been a fertile source of bickering, and bring to the Association many members who cannot be said to be the less gentlemanly, skilful or fraternal because they do not accept the Code of Ethics of the American Medical Association as the rule and guide for their conduct in professional life.

A strong desire to see everything removed that can be alleged to hamper the onward progress of the American Medical Association, was the single stimulus inciting the author of the editorial.

New York, July 25, 1892.

NECROLOGY.

Mr. William Colles, Regius Professor of Surgery at the University of Dublin, died in June, from disease of the heart and debility of age. He was one of the senior surgeons of his country, having entered upon his apprenticeship with his father as long ago as 1826. His father was the distinguished Mr. Abraham Colles, whose name has an imperishable alliance with the wrist fracture that bears his name, and who was the author of some very popular lectures on clinical surgery, early in the present century. Mr. William Colles was the Queen's surgeon in Ireland, and the holder of various college and hospital appointments covering over a half-century.

MISCELLANY.

TREASURER'S REPORT.

Presented at the Annual Meeting at Detroit, June, 1892.

Dr. Richard J. Dunglison, Treasurer, in account with the American Medical Association.

Dr. 1891.		
May 5. To cash balance as per Treasurer's report at Washington meeting	$9,427.21	
May 8. To dues from delegates and members at Washington meeting	3,505.00	
1892.		
June 4. To dues from members to date	10,012.50	
To independent receipts at office of publication, April 1, 1891, to May 15, 1892	12,580.77	
Total		$35,525.48
Cr. 1891.		
May 9. By cash paid J. Harrison White, expenses attending Washington meeting	54.75	
May 9. By Dr. D. E. Nelson, Trustee, expenses of attendance at Washington meeting	64.50	
May 9. By Dr. I. N. Love, Trustee, ditto	71.75	
May 9. By Dr. R. J. Dunglison, Treasurer, expenses of attendance at Washington meeting, telegrams, postage, expressage, etc.	53.04	
May 9. By D [illegible] ıanent Secretary, and Dr. R [illegible] (by resolution of Board of [illegible] f triennial list of members	75.00	
May 13. Dr. D. C. Patterson, Chairman Committee of Arrangements, Washington meeting, printing, rental, etc., $983.50, less donation of committee, $300	683.50	
May 14. By Dr. J. V. Shoemaker, Trustee, expenses of attendance at Washington meeting	40.00	
May 16. By Dr. I. N. Love, Trustee, expenses of attendance at Trustees' meeting, Chicago, May 13-14	54.00	
May 16. By Dr. W. W. Potter, Trustee, ditto	50.50	
May 16. By Dr. P. O. Hooper, Trustee, expenses of attending Washington and Chicago meetings	127.85

(Concluded from page 132.)

The next paper read was entitled

DARWINISM AND DISEASE.

BY WOODS HUTCHINSON, A.M., M.D.,
DES MOINES, IA.
PROFESSOR OF ANATOMY, STATE UNIVERSITY OF IOWA.

Before commencing this, to me, extremely interesting subject, I wish to say that I *do not appear before* you either as a full-fledged Darwinist or an expert pathologist, but as a mere dabbler in both, who has *succeeded in raking up, together with much mud, a* few oysters which he thinks contain pearls. Only a moiety of the collection displayed is original, but the *method of arrangement is entirely so*. The subject, of course, is an enormous one and one of which only the merest outlines can be given within the limits of *the time allotted. I fear it will seem to some of you* that setting two such "dark continents" to illuminate one another is much like calling upon one sphinx to explain another, a sort of "blind leading the blind," but as a matter of fact, even the mere inkling of the relations between the two which we have already attained makes pathology with its "magnificent schemes of decay" not only intensely interesting and *alive* but even optimistic and cheerful. I shall not attempt, of course, to define either of these subjects, Spencer's definition of Darwinism—"undifferentiated homogeneity," etc., would alone very nearly take up the time at my disposal. The first thing that might strike us is that Darwinism and pathology have apparently nothing to do with each other, nothing in common. Darwinism has to do with life and pathology with death, or the dead-room at least. But this is merely an apparent distinction, for from the Darwinist's point of view, disease is merely life out of place, life misdirected. Many processes in pathology tend towards somatic death, but death itself requires no process or influence, save that of gravity, is a mere negation, and every disease-process is a vital process on the part of the cell-groups concerned.

Perhaps a very brief outline statement of the Darwinian hypothesis as applied to cell-life would be advisable as a basis for our discussion. Cell-Darwinism may be briefly expressed as follows: That all cells have a constant tendency to vary; that these variations are capable of being inherited by their descendants; that by the action of currounding forces known as "the pressure of the environment," these variations however small, can be so "selected" that those which are of benefit to the individual are preserved and encouraged, or more correctly, that the cells possessing such favorable variations are thereby given an advantage in the struggle for existence. Finally, that by the cumulative effects of inheritance and of use and disuse, useful variations may be indefinitely preserved and developed and useless ones diminished or eliminated.

The first thing that strikes us, in looking at the subject from this point of view, is that the cells are *emphatically "the people."* It is the *insignificant* little citizen-cells of the body-republic which really control the destiny of the whole. Our "Ego" instead *of being a* "lord of creation" is a mere congressman, absolutely at the mercy of his constituents. No matter how each "voter" may have modified himself, he *still has all the possibilities* and caprices of life contained in him. Each of the cells is to be regarded as an individual and entitled to all the rights of such. *Not only so*, but each of these cells has an independent existence and though fortunately their usual action goes to nourish and is in the best interests of, the body, as a whole, yet they have also a perfect right to "life, liberty, and the pursuit of happiness" on their own account. We have been too much inclined to regard our tissue cells as our forefathers regarded all the lower animals, as if *their only excuse* for being, was the use which they might be in supporting our own lordly existences. They have rights *of their own and will assert them if we ignore them* too persistently. Indeed, most of our disease-processes seem to be due to the setting-up of the cell for itself, without regard for the welfare of the rest of the organization. These tiny units have a life-history, pedigree and inherited tendencies and characteristics. Even where individual cells array themselves in such a way as to seem actually hostile, and work great damage to the rest of the body, they are simply carrying out their own life-processes, with the best of intentions, and in many cases these same processes become actual safeguards against the spread of disease. I am convinced, that there is no such thing as malevolent or malignant action, but that on the contrary the majority of disease-processes are life-processes and intended for the service, not only of the cell itself, but also of the rest of the body. If the cells can't do just what they have been accustomed to, they will go on and do the very next best thing.

To illustrate what I mean, I might cite the processes of repair and hypertrophy, which differ only in degree: Let the stimulus or irritant be of moderate intensity and the tissue-elements promptly multiply after their kind, and increased vigor of muscle or resisting power of epidermis is developed, but let it become intense enough to cause destruction and loss of tissue and the cells can only replace part of the loss in perfection. For the remainder, they drop one step in vital rank and fill the gap with mere connective-tissue. This is the ultimate process of aseptic surgical repair, the leucocytes and fibrin merely acting as temporary "adhesive-straps" or as food for the tissue-cells in their rapid multiplication. If the lesion be accompanied by poisons which paralyze the cells or throw them into furious abortive multiplication and at the same time attract the leucocytes in such myriads that they choke and crush one another to death in thousands, then and then only is suppuration with its appalling train of surgical fever (more properly termed "unsurgical fever"), septicæmia, pyæmia, etc., set up. Inflammation is at bottom simply the forced "feeding up" of the cells, for rapid breeding to repair loss. "Whatsoever is more than this cometh of evil." The old pre-Listerian methods of surgical healing, were a good deal on the principle, so humorously attributed by Charles Lamb to the Chinese, of burning down a house every time they wanted to roast a pig.

This life-history and pedigree of our cells, of which we have spoken, is shown by innumerable instances of that curious process known as reversion,[1] the reappearance of traits and qualities peculiar to a more or less remote ancestor, but quite out of keeping in the cells themselves. These may be divided into partial, or local and general, or diffused. The partial may again be divided into Vestigia, or those affecting whole organs or parts, and Degenerations, or those affecting general groups of tissues. We will now rapidly glance at a few instances of the first of these, which are among the most interesting of all the different processes. The first and probably most striking is that curious and interesting rudiment, the external ear. As it at present exists, with its graceful outline and elaborate curves and recesses it looks as if it surely meant something, was there for some purpose; but careful experiments have shown that sound will be received just as well, if it be cut off close to the head and it is immobile so that it cannot be used as a means of determining the direction of sounds by "pricking" it. In fact, it seems utterly useless and is scarcely ornamental enough to account for its presence on that ground alone. What then is the *raison d'ctre* of this curious appendage? Its analogy to the auricle of the carnivora and herbivora is at once apparent. The tiny rudiments of muscle which are attached to it, though now utterly useless and powerless, point clearly enough to its relations in this direction, but for its origin we must go much further back. It is a familiar fact that the human embryo, in the early stages of its development, presents a distinct reversion to its fish-like ancestors, in the form of gill-slits. These, in the shark, where they are found in their greatest perfection, are protected by flaps known as opercula, or gill-covers, and these are the starting-point of the innumerable forms of the mammalian and human auricle. The external meatus is the remains of the first branchial cleft and the auricle, of the flap which covered it. But, someone will say, were not the other gill-slits provided with opercula, and if so, what has become of them? Pathology promptly answers the question. They also reappear, not at all unfrequently, in those curious appendages known as cervical auricles. These are little tags or prominences which make their appearance at various points along the anterior border of the sterno-mastoid, and the possibility of their being mere "freaks" or "sports" is emphatically negatived by the fact, first, that they contain not merely the areolar tissue of the neighborhood but fragments of cartilage and striped muscle and fat, the basal substance of the genuine auricle, and second, by the fact, that they are sometimes accompanied by and always appear at the points of opening of branchial fistula or congenital cysts of the neck which represent the partially closed lower gill-clefts. These may be either closed at both ends, forming cysts, open at one end, forming diverticula, or open at both ends, so that milk taken into the pharynx will ooze out upon the surface of the neck. In some cases these projecting growths will attain nearly half the size of the auricle proper. They are, of course, comparatively unfrequent, but a curious side light is thrown upon their probable frequence in earlier days, by the fact that many of the statues and paintings of those mythical creatures, fauns and satyrs, depict them with well-developed cervical auricles at about the position of the third branchial cleft. They are also comparatively common in goats and sheep, and it seems probable that their appearance in the sculptures and pictures is due to this fact.

These branchial clefts also furnish us with our second instance of reversion. There are situated in the fauces, a pair of little glands, which might be called the Sphynxes of philosophical anatomy. They have no recognized useful function. Their secretion is a matter of question both as to its nature and uses and yet they are one of the most annoyingly frequent seats of disease in the whole body. Our only method of defense against them appears to be the tonsillotome. The recent researches of Harrison Allen have thrown fresh light upon this subject, by showing the two so-called globular glands to be really merely pouches surrounded by glandular tissue, and a little embryological comparison reveals the interesting fact, that they are merely the dilated internal openings of the second branchial clefts, the walls of which have, so to speak, become infiltrated with lymphoid tissue, a process which, as we shall see, is very apt to take place around the extremity of any of these rudimentary fistulæ.

Another of these curious "remnants" is the appendix vermiformis of the cæcum, a structure which had no imaginable useful vocation, but a very active one apparently, in the opposite direction, as a "death trap," and which is the atrophied remains of the enormously elongated cæcum of the herbivora and quadrumana. Here again the same curious aggregation of lymphoid tissue at the end of the passage has taken place, and it is in this, more than in the interior of the appendix itself that the much dreaded perityphlitis or appendicitis takes place. Another illustration is found in those two curious little bodies known oddly enough, both by the name of the same anatomist, Luschka's tonsil in the vault of the pharynx and Luschka's gland at the tip of the coccyx. Time will not permit me to bring forward the evidence upon these points, but it is sufficient to warrant us in at least surmising that the tonsillar body and the anterior lobe of the pituitary body represent the atrophied canal of connection between the intestinal and spinal canals at their upper extremity, while the coccygeal gland together with a number of interesting tumors of this region, containing promiscuously sections of the ilium, even with villi and Peyers' patches side by side with short tubes of well-developed nervous tissue, represents the lower communication. The two tubes are now believed to have been originally continuous, so that the supposed antithesis or antipathy between "guts" and "brains" is hardly so well founded as was once imagined. The condition of central spina-bifida, on this hypothesis, is merely an instance of the familiar cystoid dilatation of an unused canal.

---

[1] For a masterly and intensely interesting presentation of this subject, see Bland Sutton's "Evolution and Disease."

Space will barely permit me to mention by name several other of the leading instances of this sort of thing. For instance, wisdom teeth, those reversions to an ancestry which had five or six molars and jaws long enough to contain them; the extra incisors which appear at the edges of the pre-maxillary bone in extreme cases of hare-lip; the process of acne, which is merely an atrophied hair-gland, or as we call it, sebaceous gland, endeavoring to produce its normal hirsute tissue at the period of puperty; the frequency of Pott's fracture of the fibula in spite of the "splinting" effect of the tibia, which seems probably due to the fact that the fibula is a rapidly atrophying relic which may possibly ultimately disappear, as it has already done in equines, bovines and most other mammals. The two bones are of equal size at the third month in the embryo as well as in the manatee and some of the quadrumana. The great preponderance of equino-varus over all other forms of club foot, it being the normal position of the foot not only in our quadrumanous relatives but also in the embryo up to the seventh month. These are only a few of the most important of these partial reversions, for the tip of the forefinger can scarcely be laid upon a single part of the body which will not under some circumstances furnish us with one or more such proofs of our pre-human descent.

We now come to the other form of partial reversion, in which the change is confined to certain tissue groups and is much simpler in its nature, being what we term, merely a degeneration. These are the familiar four, arranged both in the order of their frequency and lack of vitality: The Caseous, Calcareous, Fatty and Fibroid. The first two of these can hardly be dignified by the term of vital process. They are simply the breaking down of the protoplasm of the cell into simpler and less highly-vitalized forms, and yet organic forms for all that. But the second of these is clearly only a form of vital action gone wrong, differing only from bone formation in that the cell dies or withdraws entirely and gives place to the inorganic lime salt instead of arranging it in such a way that it or its successors or appointees can still control the region. In other words, it vacates the premises entirely, instead of merely renting them. In many instances it is in itself a genuine conservative process changing an infective focus into a fixed and harmless foreign body, as in the case of tubercle and some forms of encystment. It also has obvious analogues in the processes of the protozoa and polyzoa, being the method by which the coral insect builds his reef, the globigerina forms the chalk beds and the squid his otoliths.

In fatty infiltration and degeneration we have another vital process gone very wrong indeed. A process which, under normal circumstances, is the very "savings bank system" of the body; protects the delicate centers from every mechanical or caloric shock, lubricates the movements of the muscles, and is simply indispensable as a store-house of energy. It is, however, so easy to form that it is no uncommon thing for higher cells in all parts of the body to produce it instead of their legitimate product, through laziness or enforced idleness, in some cases at the expense of their own protoplasm. If there be a sufficient number of healthy cells in the neighborhood to promptly devour the fat and work it up into fresh tissue, it is in some lights almost a conservative change, but if not, then results of all degrees of disastrousness may ensue. This process may take place outside of the body just as well, as the familiar instances of the formation of adipocere. and the ripening of cheese bear witness.

The highest and most important, and, in many cases, most deadly of these degenerations is the fibroid. Here we have a reversion of a considerably higher character and more difficult of accomplishment on the part of the cells and one, which, in intention at least, would appear to be always conservative, though its results may often be far otherwise. As seen in the formation of scar tissue, in the fibrous envelopes around tubercle, in the wall of abscesses, in the coating of encysted foreign bodies, and in the repair of tendons, it simply is indispensible, but on the other hand where it takes the place of more highly specialized tissues like kidney epithelium or the gray matter of the spinal cord, it is one of the most dangerous and unmanageable of processes. The rationale of its formation is a highly disputed question, but the most probable explanation appears to be that it is an actual substitution by the cells involved of a lower for a higher form of reproductive product. This may be due to almost any form of over-stimulation, whether by over-work, excessive mechanical tension or pressure, or by the presence of a virus, and would appear to be associated with a sthenic condition of the system rather than an asthenic.

We have heretofore been considering diseases in which the process is merely one of degeneration of the cell-protoplasm itself, and has little or no direct connection with the individual vital processes of the cell as a unit. We now, however, have a form of disease which seems to consist of what we might term a reversion of function; a production on the part of the cell of an incomplete metabolic result which was normal in one of its comparatively remote ancestors. There is but one disease of this form, but it is a perfect "Pandora's box" of the evils to which flesh is heir, and that is the celebrated "*morbus dominorum* and *dominus morborum*"—gout, or as it is known at the present day, "Lithæmia." With all its innumerable varieties of manifestions, it seems at bottom to consist in a tendency on the part of the hepatic cells to form uric acid instead of urea. This, of course, as will readily be seen, is merely a reversion to the avian or reptilian stage in the ancestors of the liver cells, in both of which large classes, the elimination of the nitrogenous materials of the food is solely in the form of uric acid; indeed, Garrod remarks that "our gouty patients seem to be a sort of birds." The world-wide prevalence of this tendency has, I think, been very much under-estimated. In spite of the fact that gout is supposed to be, and in its more frank manifestations, unquestionably is, a rare disease in this country, I am satisfied that a large portion of our celebrated national "dyspepsia," most of our "biliousness," all of our lumbago, muscular rheumatism and not a little of our neuralgia are due to this degenerative tendency, to the loading of the blood with the half finished products of the hepatic cells. And, indeed, from the investigations of Fothergill, it would seem probable that the initial change in the terrible Bright's disease itself, is first a hyperplasia of the muscular coat of the arterioles, due to irritation caused by the presence of these substances in the blood, ending, as all over-stimulation will, in fibroid degeneration, the "arterio-capillary fibrosis." If this process be a reversion to the point of departure of two of the largest branches from the main trunk of our family tree, its wide-spread prevalence is readily explainable. The methods which have proved most permanently beneficial in its treatment would appear to point in the same direction, being principally such as will improve the tone of the system in general and the liver-cells in particular, supplying them with abundance of fresh air, sun-light and vigorous exercise. In short, all those means which would lift us as far above the reptilian stage as possible.

We still have a large number of disease-processes, probably the most interesting, to the pathologist, of all the series, which may, perhaps, be best described as "reproductive" reversions. I refer to the so-called "new-growths" or "new-formations," and would arrange them in the following order of ascending vitality and perfection. This may seem a wanton infraction of some of the recognized rules of pathological classification but I am convinced that they are related, at least remotely, in some such way. They comprise: 1, and lowest of all, Tubercle; 2. Gumma; 3. Malignant tumors; 4. Benign tumors; and 5, and highest of all, Hypertrophy, or regeneration. In all these, the essential factor appears to be a tremendous stimulation of the function of reproduction on the part of the individual cells of the group affected, with results ranging in perfection, from the lowest to the highest of the series.

In tubercle, the process would appear to be one of rapid multiplication of connective-tissue cells by endogenous fission—"giant cells"—at various foci, the determining cause apparently being starvation, under-feeding, or mal-nutrition of the cells concerned, thus leading them to rush hurriedly into reproduction, as a means of avoiding extinction, much in the same way as plants, grown in sterile soil, run to seed. Animals hard pressed by their environment appear to become more prolific, and even the human family itself, where the food is scantiest and struggle severest, appears to have the highest degree of fertility. The perfection of most of our improved varieties of animals or plants seems to be dependent largely upon the lateness of the period to which the reproductive act can be postponed. The products of tubercular multiplication, born in a soil already impoverished, remote from the blood-vessels, bear the stamp of their parental weakness and are not only incapable of continued existence, but even of any form of degeneration except the caseous. They can set up fibroid degeneration in the sturdier tissues surrounding them, but all that they themselves seem capable of, is to rot and make a meal of carrion for the tubercle bacillus. What part the bacilli play in this process is hard to determine, but it would seem a secondary one as they do not usually appear until after the tubercular formation has taken place and caseation set in. The enormous frequency of the tubercular process in the human subject—it now being estimated that it occurs in nearly 60 per cent. of all human beings at some period of their lives—the great importance of the pre-tubercular condition, the readiness with which the disease is induced in animals, merely by confinement or starvation (nearly two-thirds of the deaths in confinement of animals being due to this cause), the utter failure of all bactericide remedies and the gratifying results obtained from fresh air, sun-light, high elevation and outdoor exercise at any reasonable stage of the disease, all point in the direction of its being due to some general tissue tendency, rather than to a specific external cause. It might almost be termed the "starvation reflex" of all living tissue.

In the second process, viz., gummatous formation, we have a similar but more violent determination on the part of the tissue-cells in various localities to "be fruitful and multiply" no matter what comes of it. The cause in this instance appears to be a specific virus. It differs in that the formation is much more rapid, is participated in by a larger body of cells, and the resulting product is a stage higher in the grade of vitality. It is capable not only of maintaining its existence, in the form in which we find it, for some little period of time, but also of the comparatively valuable and conservative process of fibroid degeneration. A gumma may result in a mass of scar tissue, a tubercle, only in a caseous or calcareous nodule.

The next rank in order of perfection, is that of the so-called malignant tumors. Here the cells, instead of being merely amœba-like, with simply a capacity for degeneration, bear a more or less ghastly resemblance to the parent cell. If the connective tissue be the starting point, we have the sarcoma, dangerous just in proportion to the imperfection of the offspring produced, ranging from the nearly amœba-like or embryonic "small round-cell," with its intense malignity, to the almost benign "spindle-cell" or "myeloid." If the glandular or epithelial tissue be the starting point, we have the deadly brood of carcinomata, again varying in their dangerousness, according to the imperfection of the spurious product turned out. A cancer may be described as a parody upon gland tissue—and a hideous parody it is. Here there seems to be little difficulty in determining one, at least, of the predisposing causes, and that is, senility of tissue, its having outlived its usefulness. The mammary gland in the female, after the child-bearing period, the uterus at the same period, and the wrinkling, shrivelling lip or baggy eyelid of the toothless old man, furnish an enormous proportion of the cases of this terrible "rebellion of the cells," as it has been well called.

The next class, although of apparently less importance from a pathological standpoint, is quite an extensive one, and includes the so-called benign tumors. Here the reproductive process is orderly and perfect in and of itself, and is merely not in harmony with the demands of the rest of the system. We are utterly in the dark as to the predisposing cause. All that we know is that certain groups of cells in the various parts of the body suddenly commence to reproduce themselves in a perfectly orderly and methodical manner, but without any reference to their result upon the general body system, with which they interfere simply by their bulk or mechanical properties. Here again the frequency is in direct relation to the simplicity, or to the easiness, so to speak, of the imitation. The simplest tissue to imitate on the part of any of the body cells is the fatty, and we find lipomata at the head of the list, both in point of frequency and simplicity. Next, in the same double order, come the fibromata, a little more difficult of production, less frequent, but more dangerous, then the myomata or unstriped muscle tumors, and the more complex but much less common adenomata, with their astonishing mimicry of healthy glandular tissue, and last and rarest of all, because most highly specialized and most difficult of imitation, the neuromata and rhabdomyomata or striped muscle tumors.

The apex of the pyramid is reached by the processes of physiological or compensatory hypertrophy and surgical regeneration, where the reproductive product is not only perfect in itself, but in accurate harmony with the needs of the whole system, the whole series varying in its benignity or malignity in proportion to the remoteness, so to speak, of its reversion. Between the almost universal and fearfully disastrous tubercle, with its mere possibility of caseation, to the gloriously beneficent physiological hypertrophy of the uterus or heart or the every-day miracle of surgical regeneration, it is merely a question of the vital perfection of the daughter-cells.

Would time permit I should like to take up the still more individualized action of the cells in the various forms of leucocytosis in its bearing upon this theory. The whole process of fever and inflammation would appear to be a genuine battle of cells begun by a skirmish-line of leucocyte mounted police and continued by seried ranks of macrophage militia, recruited from the sturdy citizen-cells of the fixed tissues. The wonderful and fascinating process of phagocytosis is a complete epic poem of more than Homeric interest. The extraordinary facts of the immunity-problem prove the eminent ability of the cells of the body to defend themselves against all comers, however evilly disposed, while the singular rhythm of weeks, or lunar months, displayed by the reproductive process, the menstrual functions, the intermittences in the malarial fevers and even by the period of lysis and crisis of various diseases, would appear at least to suggest an impress upon the fixed cells of our body which has been stamped upon them from the time that their ancestors lay upon the sea-beach and depended upon the rhythmic rise and fall of the tides, for their very existence.

I have no doubt that to the most of you this will appear merely a matter of possibly interesting, but utterly impracticable and useless theory. But, to my mind, the practical teaching of the suggestion is its most valuable part. Not by a search for specifics or germicides or by efforts to extinguish germs which are a million times as numerous as the human family and in their proper place quite as useful—our best friends instead of our deadliest enemies—but by an untiring and intelligent watchfulness to grasp every means which can improve nutrition, elevate the standard of vitality, increase the beauty and symmetry of and in every way possible strengthen and develop these wonderful bodies of ours is our noble aim to be attained. A healthy stomach or bronchus is the hottest place a disease germ can drop into. The most powerful enemy of death and disease is life in its most vigorous form and our mission, as already beautifully paraphrased in religious imagry, is that our patients "might have life and that they might have it more abundantly."

Dr. Herrick, of Cleveland, expressed gratitude to the author of the paper. It looks, he said, like getting back to solid ground, and I heartily commend its contents.

Dr. Eckert, of Iowa, stated that the paper met his approval in several ways. He thought it broke down the popular misconception of Darwinism. He thought that it also harmonized modern views of anatomy and pathology.

Owing to the lateness of the hour, and the happy anticipation of an excursion on Detroit river, under the auspices of the local profession, the papers remaining on the program were read by title, and the Section adjourned.

EUROPHEN, WITH CLINICAL REFERENCE TO EUROPHEN AND EUROPHEN-ARISTOL.

Read by title in the Section of Practice of Medicine at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY JOHN V. SHOEMAKER, A.M., M.D.,
OF PHILADELPHIA, PA.

Europhen results from the action of iodine upon isobutylorthocresol in a solution of iodine of potassium.[1] The product, as prepared and sent out by the Farbenfabriken, formerly Friedrich Bayer & Co., of Elberfeld, appears in the form of a fine, soft amorphous powder, slightly resinous to the touch, of a light yellow color, destitute of taste and having a faint, not unpleasant odor which recalls that of saffron. This odor is almost entirely lost when europhen is made into a mixture or solution. Europhen is insoluble in water and glycerine, soluble in alcohol, ether, chloroform and fixed oils. When exposed to a heat of 160° F., europhen thickens and at 230° F., is converted into a clear brown fluid. The specific gravity of europhen is five times less than that of iodoform and half that of iodol. The body is easily decomposed by light and heat. It should, therefore, be kept in a dark, dry and cold place and its solutions be made at a low temperature.

The average proportion of iodine contained in europhen is 27.6 per cent. A small precipitate, consisting of an organic iodine compound and soluble in water, forms from solutions of europhen. It is likewise present in the dry powder. A very small percentage of free iodine, formed during the drying and which cannot be removed from the product, is present in europhen. Solutions of europhen in alcohol and ether slowly liberate small amounts of iodine. Europhen should never be mixed with fat combined with starch. It is incompatible with metallic oxide and the salts of mercury. Fats free from starch are good excipients for europhen, and lanolin is particularly appropriate, since the large amount of water which it is capable of taking up promotes the liberation of the soluble iodine compound.

Siebel has determined that the presence of europhen in culture-media prevents the development of pathogenetic microörganisms by a chemical action and arrests the formation of products of decomposition.

Europhen adheres firmly to cutaneous and mucous surfaces with which it is brought in contact. Under the influence of liquid pathological products, it is believed to slowly give off small quantities of iodine which entering into immediate action, form the soluble organic compound of iodine to which reference has been made. When taken by the mouth, europhen undergoes but little change as it passes through the system. A very small proportion of iodine appears in the urine after its administration. It is removed from the body with the fæces for the most part unchanged. The alteration is scarcely greater when dissolved in oil and it can be subcutaneously injected. Europhen is, consequently, a nontoxic substance. Two or three drachms have been given to dogs without any ill effects and fifteen grains have been taken by the human subject with no more serious result than a slight sensation of weight in the stomach.

---

[1] The physical and chemical properties of europhen have been carefully studied by Dr. F. Goldmann and are described in the *Pharmaceutische Zeitung*, July 15, 1891.

The first clinical experiments with europhen were undertaken by Dr. P. J. Eichhoff of Elberfeld, who published in the *Therapeutische Monatshefte* for July, 1891,the results of its employment in a series of cases. A chronic and obstinate ulcer of the leg, which had resisted the action of many other remedies, healed in six weeks under the application of a ten per cent. ointment of europhen. A deep and sluggish ulcer, dependent upon a marked varicose condition of the limb, was almost entirely cicatrized in five weeks by the same method of treatment. Several chancres were healed and their induration removed by the insufflation of europhen upon their surface in periods of from two to four weeks. The application of the powder removed, in three cases, large condylomata of the anus and genitalia in 10, 17 and 28 days. A case of syphilitic papules with leucoderma and marked thickening of both labia majora was relieved in the same manner. At the end of two weeks the papules had disappeared, but slight pigmentation remained and the labia were reduced nearly to their normal size. An ulcerated scrofuloderma of the arm in a girl of fourteen years cicatrized under a europhen ointment in 19 days. A ten per cent. salve was first used but giving rise to irritative eczema of the surrounding skin, was after three days, replaced by a five per cent. ointment. The irritation persisting in the same degree, however, at the end of three more days, a one per cent. preparation was applied. The healing process continued at an undiminished rate,and the eczema soon subsided. In a case of lupus vulgaris, after scraping the softened nodules with a sharp spoon, europhen powder was dusted upon the surface and a firm smooth scar was obtained by the eighteenth day. A burn of the third degree was cicatrized by a one per cent. ointment in 20 days. Chancroids were rapidly healed by application of the powder. In several cases of parasitic eczema europhen occasioned little or no improvement and was discontinued. The result was the same in a case of impetiginous eczema. Europhen in the form of a ten per cent. ointment, was less beneficial in a case of psoriasis than either aristol or tar. In a case of favus, likewise, europhen proved of no avail. An injection of europhen in olive oil and acacia was disadvantageous in two cases of acute gonorrhœa. It gave rise to pain and was abandoned. In a case of gonorrhœa of the urethra and cervix uteri, however, under the care of Dr. Siefert, of Wurzburg, a tampon impregnated with europhen caused speedy diminution of the discharge and disappearance of the gonococci. In a case of endometritis with erosions of the os uteri and a copious seropurulent discharge, a decided improvement followed. Dr. Petersen, of Wurzburg, reports satisfactory results from the insufflation of europhen in the rhinitis of scrofulous children, attended with profuse discharge and eczema of the nares. He thinks from his experience in three cases, that the same method of treatment will probably be found useful in acute rhinitis. Europhen was also of value after operative procedures within the nose. A ten per cent. ointment of europhen was, in the clinic of Dr. Siefert, extremely efficacious in the treatment of both the simple and fetid forms of atropic rhinitis. The preparation was introduced upon cotton tampons, which were allowed to remain in place for about half an hour. The dryness gradually lessened, secretion increased, crusts and offensive odor disappeared. From one of the clinics of Heidelberg, Dr. von Szoldrski reports favorable influence in three cases of laryngeal tuberculosis with abundant muco-purulent secretion. This writer also testifies to its worth after operations upon the nose and larynx. Dr. Lowenstein has obtained good results from the use of europhen in perforating ulcer of the septum of the nose and in epistaxis dependent upon erosion of the septum. Dr. A. Nolda, has successfully used europhen in three cases of suppurative otitis media, in leg ulcer, chancre and chancroid. In the last named affection, a comparative study led him to esteem europhen as being more efficacious than iodoform. On account of its lightness, a given quantity of the former will cover five times as much surface as the same amount of the latter substance. Dr. Vulpius states that in the clinic of Professor Czerny, in Heidelberg, europhen has been employed with satisfaction in the treatment of accidental and surgical wounds, osteomyelitis and tubercular ulcers. A communication has been made by Dr. Juan Santas Termandez in regard to the value of europhen in ocular affections. He has employed this remedy in conjunctivitis, keratitis, traumatism and after operations, generally in the form of a one per cent. ointment.

Dr. Eichhoff has made experiments with hypodermic injections of europhen on constitutional syphilis. He injected from one-half to one and one-half grains dissolved in olive oil once daily and states that while in some cases the results were decidedly encouraging he is not able to recommend the method for general adoption. Dr. Gaudin, of Paris, has written favorably of the effect of hypodermic injections of europhen in tertiary syphilide in which he considers it more effective than in the secondary form of the disease.

Both aristol and europhen are prepared by the same firm of manufacturing chemists and have similar therapeutic powers. Both substances are proposed as substitutes for iodoform, over which they possess the decided advantage of comparative absence of odor. It has been thought that the sphere of activity of each product may be enlarged by combinations and with this view, a mixture of equal parts is offered under the name of europhen-aristol. The mixed product is an impalpable powder, of a buff color, a rather more pleasantly aromatic odor than europhen and somewhat more resinous to the touch. It will probably be found superior in adhesiveness to europhen. The properties and uses of aristol I have already described. (*Medical Bulletin*, June, 1891.)

Specimens of europhen and europhen-aristol having been placed in my hands, I have carefully studied their effects in a number of cases to which they seemed applicable and believe, that europhen, like its predecessor, aristol, is entitled to rank as an acquisition to the list of therapeutic agents. My experience relates especially to accidents or diseases involving the integument.

Primary union promptly takes place in incised wounds when,after being cleansed and approximated, powdered europhen is kept applied to the surface. This substance, like aristol will, no doubt, prove efficient as a dressing to many forms of operative wounds. In contused and larcerated wounds, inflammatory action is abated and destruction of tissue is minimized. The surface is maintained in a dry and aseptic condition and the loss of tissue is solely dependent upon the extent of interference with the capillary circulation of the injured part. The devitalized tissue is protected from the action of pathogenetic organisms, which so often and so seriously complicates the case in these varieties of traumatisms. Chronic ulcers of the leg were favorably influenced by both the pure and mixed powder. One case in particular, I may cite by way of illustration. A large and indolent sore, of unhealthy appearance, had long been seated upon the lower third of the left leg of an old man. The veins of the limb were enlarged, tortuous, prominent and engorged. The granulations were feebly organized, the surface was covered with sanious pus, was sensitive and prone to bleed. The edges were callous and the lesion was surrounded by a zone of lividity. Many remedies had been used with little or no effect, and the patient, discouraged by ill success, had perhaps, neglected scrupulous and constant attention to cleanliness. As a preliminary measure, I directed the surface to be cleansed with a weak lukewarm solution of carbolic acid and when the inflammatory products had, as far as possible, been removed, to be strewn with europhen-aristol powder, covered with a layer of borated absorbent cotton and moderate compression exerted by means of a roller bandage carried from the foot to above the knee. Together with this local therapy, appropriate dietetic and constitutional measures were instituted and the patient was directed to rest his limbs, as much as possible, in the horizontal position. A highly gratifying effect was produced. In the course of ten days, the character of the surface completely changed. Healthy granulations made their appearance, a course of repair was inaugurated which thenceforward proceeded steadily without interruption and at the end of four weeks, the surface was soundly cicatrized. An elastic bandage was ordered for the sake of supporting the toneless and dilated veins and the patient dismissed.

A young girl, 19 years of age, presented, upon the left side of the neck the characteristic and unsightly ulcer resulting from the degeneration of a scrofulous gland with destruction of the overlying integument. The patient was of fair complexion, pale and rather delicate in appearance, but free from any sign or symptom of pulmonary disease. A cicatrix upon the right side of the neck indicated the presence of former ulceration. The surface of the sore was uneven, covered by a grayish deposit and from it issued a thin puriform discharge. The edges were undermined and of a dull red color. Constitutional treatment was ordered and the ulcer was dressed with powdered europhen held in place with a pad of borated cotton. Improvement soon began, the suppuration diminished, the grayish exudation disappeared, the granulations took on a healthy aspect and at the expiration of about three weeks, I was able to discharge the patient with a freshly formed and healthy scar occupying the site of the lesion.

A woman, aged 26 years, long the subject of lupus vulgaris, upon whose face both nodules and ulcers were present, who had been treated by many physicians and by almost every known method, was chosen as an excellent case by which to test the virtue of the new remedy. Twice or thrice daily, europhen in powder was freely dusted over the ulcerated surface which was, in addition, irrigated every day with a carbolized solution. Amendment was manifest by the end of a week and in three months' time, the patient was discharged cured, at least for the present. Whether relapse shall occur remains, of course, for the future to decide. In another case, of still greater chronicity and obstinacy, an equally favorable result was obtained though the progress of repair was more tardy.

A man, aged 68 years, of good habits, came to the Medico-Chirurgical Hospital on account of a superficial ulcer, situated upon the upper third and toward the outer border of the right thigh, about five inches below Poupart's ligament. The disease had begun as a hard papule which was the size of a buckshot when first observed. After some months the skin had cracked and given exit to a thin, blood-stained fluid. This discharge soon dried and formed a thin, brown scab. Subsequently a roundish ulcer, with hard edges and a red base had formed. The patient was undoubtedly afflicted with the superficial form of epithelioma. The ulcer, which had been cauterized and curetted to no avail, was the seat of pain. Europhen in powder was at first applied but not being followed by much improvement, the ointment form was resorted to and after several trials, a preparation containing from three to four drachms of europhen to the ounce of a fatty base, was adopted as the most suitable to the morbid condition. Under this medication, the pain subsided and healthy granulations slowly sprang up, gradually spreading until the raw surface was entirely cicatrized. The ulcer was healed at the end of about four months after beginning the course of treatment. In another case, that of a woman, fifty years of age, a small epithelial ulcer was seated upon the left ala of the nose. It had seemed in the beginning, to be nothing more dangerous than a wart, sometimes a stinging, darting pain would be felt in the growth. At length the skin broke, a little sanious discharge escaped, dried into a brown crust which the patient picked off, exposing a deep red, raw but dry surface with hardened edges. This ulcer grew gradually and slowly in extent, and when the patient applied for relief, involved nearly all the surface covering the ala and the cartilage. Aristol was first used upon this lesion but although some improvement was observed, the ulcer still remained open and irritable. Europhen was next employed with about the same result. The sore manifested, a slight disposition to heal but no decided gain could be detected. For some weeks the two remedies were then used alternately but still the condition remained comparatively unchanged. Finally the mixture of equal parts of europhen and aristol was used, when the ulcer began to gradually but steadily heal from the bottom and in about ten weeks a well marked cicatrix had formed.

The upper lip of a young man was invaded by sycosis, was red, swollen, surmounted by papules, pustules, scales and crusts. The lesions were numerous and had coalesced. Some of the pustules had freshly ruptured when he first came under my care, and the hair, which he had as closely trimmed as possible, was matted together in places. The patient suffered considerably from the sensations of heat, smarting and tension in the affected part. After the crusts had been removed by the oil of ergot, I directed the part to be thoroughly cleansed by a weak lotion containing hamamelis, after which a 10 per cent. ointment of europhen was placed upon the surface. The hair being closely cut, no difficulty was experienced in making the application. The subjective symptoms were rapidly alleviated and the objective manifestations soon began to improve. The ointment was placed upon the surface several times during the day, and its use was eventually followed by a complete cure.

After the necrosed tissue has been expelled, europhen powder, dusted upon the surface of a carbuncle, accelerates the work of repair. I made use, in carbuncle, of the mixed powder, europhen-aristol, with the same good result.

A young man, aged 18 years, consulted me on account of papular acne upon the face and back, from which he experienced great annoyance. The lesions were abundant upon the cheeks and chin, were interspersed with comedones, and the patient, not otherwise ill-looking, was indeed sadly disfigured. Many external remedies had been used upon his face with little or no benefit; the red and indurated papules remained. The employment of a suitable diet, with some attention to the digestive organs, combined with europhen ointment, soon effected a change. The strength of the ointment varied from 1 to 2 drachms of europhen to the ounce of excipient. Under this treatment the lesions soon began to decrease in size and number, and at length disappeared under the use of the external treatment.

A middle-aged woman was sent to me, whose face exhibited a typical example of the second stage of rosacea. Upon the forehead, nose, cheeks and chin, the injected capillaries could be seen as bright red streaks, running parallel to each other in some situations, as upon the ala of the nose, while in other regions, as upon the cheeks and chin, they were arranged in tortuous curves. Some of the vesicles were of considerable size. The skin was rough and thickened, and here and there upon the face were scattered papules and pustules. Locally, I directed the following lotion to be used:

℞. Europhen, ʒij.
Glycerini, ℥ij.
Spir. odorati q. s. ad., ℥j.
M. Sig. For external use.

By the persistent employment of the measures recommended, the papules gradually retroceded, the pustules disappeared and the capillary injection in great measure subsided. Altogether the improvement was gratifying alike to physician and patient.

In several cases of facial erysipelas notable amelioration attended the use of an ointment containing from 10 to 20 grs. of europhen to the ounce. The smarting and burning was soon relieved, the swelling diminished and the eruption ceased to spread. The absence of offensive odor is an undoubted advantage which this substance possesses over ichthyol, which has of late been highly recommended and widely used as a topical agent in the treatment of erysipelas. In dermatitis caused by contact with rhus toxicodendron, the application of an ointment beginning with 10 grs. and gradually increased to 1 drachm of europhen is well adapted to serve as a dusting powder upon the surface, after the vesicles have been ruptured. I made use of this remedy, likewise, in several cases of herpes zoster which came under my care. The pain, or at least, the distressing burning and smarting sensations produced by the lesions of zona, are generally mitigated by the use of a dry powder. It is difficult, however, to keep the lesions covered, and for this reason, the slight stickiness of the europhen powder, enabling it to cling closely to the surface upon which it is placed, renders it an excellent medicament in herpes zoster when situated, as it so often is, upon the side of the chest. In the form of a powder, I have also found it of advantage in seborrhœa oleosa. In this condition, I have directed my patients to wash the affected region, before going to bed, with a lukewarm solution of chamomile or boro-glyceride soap, and after thoroughly drying the skin, to cover the surface thoroughly with powdered europhen. The result has been quite satisfactory. The powder remains in place, absorbs the greasy discharge and exerts a tonic and corrective effect upon the affected glands. The simultaneous internal exhibition of the tincture of hoang-nan in the dose of 15 to 30 drops, three times a day, will coöperate in bringing about a cure.

An ointment of europhen appeared to be of assistance in a case of alopecia circumscripta. The patient was a middle-aged merchant of good physique and a vigorous growth of hair, but who had been subject for more than a year to the double strain of keen anxiety and overwork. The hair suddenly fell out in spots, leaving several denuded and unsightly patches upon the scalp. In this instance, the origin of the affection was evidently the perverted action of the nervous system. A certain number of cases are seen which lend probability to the view that alopecia circumscripta sometimes depends upon the growth of a parasite. In the case of which I write, the europhen salve was conjoined with the local use of galvanism, and I insisted strongly that as far as possible, the tone of mind and habit of thought should be changed.

As a rule, no instant effect will follow the application of europhen powder upon an unbroken surface. That in certain conditions in which the vitality of tissue is lowered, it may give rise to an irritative eczema, is shown by one of Dr. Eichhoff's cases. It has, however, sometimes appeared to me to exert a stimulant effect upon the integument and its glands. I have seen several cases of hyperidrosis in which the excessive secretion was manifestly restrained by frequently dusting the surface with europhen powder. To the unfortunate sufferers from bromidrosis of the feet, the europhen-aristol powder has given decided relief, arresting the discharge and removing its offensive odor. At night the feet should be bathed in a slightly stimulating bath, containing mustard-flour, salt or alum, and after being dried by brisk rubbing with a towel, the powder is sprinkled liberally upon the surface and between the toes. By day the powder is strewn in the stockings.

I have derived benefit from the use of europhen or the compound powder in a number of cases of eczema of different forms and stages. In acute vesicular eczema, europhen powder combined with subnitrate of bismuth has reduced the local inflammation, absorbed the serous exudation, allayed the heat and itching. A case of chronic eczema affecting the hands and feet was cured by the persistent use of an ointment composed of 1 drachm increased to 2 drachms of europhen to the ounce of lanolin. Eczema of the hands and feet is an obstinate affection. The fissures which form are kept open by manual occupation or in the act of walking, the skin becomes thickened and the fissures are the seat of pain. A case illustrative of this condition was markedly benefited by the application of europhen-aristol. The patient was a man, aged about 40 years, who had long been afflicted upon the soles of both feet. The surface was painful, long and deep fissures had formed, from which issued a blood-stained serum, vesicles and fissures also existed between the toes. The patient was teased with constant itching, and locomotion was impossible. The treatment adopted was the dusting of europhen-aristol powder between the inter-digital spaces, and the application to the plantar surface of an unguent containing from 1 to 2 drachms of the same powder to the ounce of rose water ointment. The pain and itching soon began to decrease and the fissures to heal. In the course of a week, the patient could endure shoes, and a few days later he was able to go to his place of business. At the end of eight weeks he returned, free from the least trace of eczema. A distant rheumatic diathesis was present in this case, and an internal treatment was addressed to this underlying condition.

A woman, aged 37 years, sought my advice on account of a psoriasis from which she had suffered since girlhood. Patches were to be seen upon various parts of the body. At times the condition would improve, either as a result of medication or spontaneously, the disease would remain quiescent, but after an interval of uncertain periods, an exacerbation would occur. It was during one of these relapses that I first saw the patient. Small patches were interspersed with large oval areas, upon which the characteristic grayish scales were seated. Here and there patches had coalesced, giving rise to fantastically shaped lesions. In some places the scales had become detached, and a thickened, reddened and slightly elevated surface was exposed. The case, in fact, presented a typical picture of psoriasis. A uric acid diathesis was evidently present in this instance, and probably accounts for the inveteracy of the malady. To the constitutional condition an appropriate therapy, which will not here be discussed, was given, while the local medication consisted in the application of a europhen-aristol ointment, the scales having been previously, as far as possible, removed by the usual methods. The ointment was at first made in the proportion of 1 drachm to the ounce of fat, but the strength was gradually raised to 3 drachms. The local measures obviously exerted a favorable influence upon the lesions. The amount of infiltration was markedly lessened, and she was dismissed with directions to continue the use of the ointment at any time that redness appeared. Aristol I had found beneficial in psoriasis, but the europhen-aristol seemed to produce a more decided as well as a more rapid effect.

In syphilis, my experience with europhen and aristol has been principally confined to the open lesions of the late secondary period. Upon ulcers and upon syphilitic rupia, after the latter had been cleared of its accumulated crusts, both the europhen powder alone and the mixture with aristol stimulated the work of repair. I have every reason to regard them as valuable adjuncts to the constitutional treatment. Upon ulcers, often of considerable size, found upon the limbs in late syphilis, especially in those patients who lead dissipated lives, the mixed powder was of advantage. Chancres, chancroids and open buboes are also benefited by the same application.

In the foregoing summary of cases in which europhen has been employed with advantage, the aim has been to record the facts which I have personally observed. The cases briefly glanced at have been selected from a number as being suitable tests of the power of europhen. The solubility of europhen in olive oil renders it well adapted for injection into pus cavities, sinuses and fistulæ. The freedom from offensive odor is a point in its favor. An excellent property of europhen is that it will not harden into compact cakes upon the surface to which it is applied. As an antiseptic dressing, europhen is of value, and the absence of toxicity is another point in its favor. The harmlessness and not unpleasant smell commend this substance in the surgical affections of children and in gynecological practice. That the mixture of europhen and aristol adds something to the efficiency of each, is shown by a case of epithelioma, in which first one and then the other substance were used alone without effecting much benefit, while the mixed products speedily instituted a course of improvement. In some patients the powder acts more beneficially, while in others an ointment is productive of more favorable results. It may be necessary to increase or decrease the strength of the ointment according to the circumstances of the case. I have generally found that a proportion of 1 drachm of europhen to the ounce of excipient makes an efficacious ointment.

A FEW NOTES ON THE MECHANICAL THERAPEUTICS OF OSSEOUS AND MEDULLARY LESIONS OF THE SPINE.

Read by title in the Section of Practice of Medicine at the Forty-third annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY THOMAS H. MANLEY, A.M., M.D.,
OF NEW YORK.

Perhaps in no department of medical science during the latter half of the present century has there been any greater, or as great advance, as in that which embraces within its scope the relief or permanent cure of physical infirmities by mechanical measures. The enormous progress in modernly applied physics, has completely revolutionized pathology, and rendered in many instances, precise accuracy in the diagnosis of disease possible. In nothing, however, have the practical, beneficent influences of these advances been so conspicuous or happily appreciated as in the treatment of disease.

Very naturally, we Americans feel a just pride in the share which members of our profession have contributed; for, although this must go into history as the greatest inventive century that the world has ever witnessed, it must likewise be conceded by the impartial historian, that Americans have, in this direction, occupied the foremost rank, and given to posterity such discoveries and inventions as will endure as long as time itself.

Little time was lost in utilizing and appropriating those principles of mechanics, in the surgical art, which were first mainly limited to the arts and industries. In fact, to-day one can scarcely conceive how it is possible, for the art of mechanical therapeutics to be much further extended. Thus, we thought, smarting and tension in the affected part. After the crusts had been removed by the oil of ergot, I directed the part to be thoroughly cleansed by a weak lotion containing hamamelis, after which a 10 per cent. ointment of europhen was placed upon the surface. The hair being closely cut, no difficulty was experienced in making the application. The subjective symptoms were rapidly alleviated and the objective manifestations soon began to improve. The ointment was placed upon the surface several times during the day, and its use was eventually followed by a complete cure.

After the necrosed tissue has been expelled, europhen powder, dusted upon the surface of a carbuncle, accelerates the work of repair. I made use, in carbuncle, of the mixed powder, europhen-aristol, with the same good result.

A young man, aged 18 years, consulted me on account of papular acne upon the face and back, from which he experienced great annoyance. The lesions were abundant upon the cheeks and chin, were interspersed with comedones, and the patient, not otherwise ill-looking, was indeed sadly disfigured. Many external remedies had been used upon his face with little or no benefit; the red and indurated papules remained. The employment of a suitable diet, with some attention to the digestive organs, combined with europhen ointment, soon effected a change. The strength of the ointment varied from 1 to 2 drachms of europhen to the ounce of excipient. Under this treatment the lesions soon began to decrease in size and number, and at length disappeared under the use of the external treatment.

A middle-aged woman was sent to me, whose face exhibited a typical example of the second stage of rosacea. Upon the forehead, nose, cheeks and chin, the injected capillaries could be seen as bright red streaks, running parallel to each other in some situations, as upon the ala of the nose, while in other regions, as upon the cheeks and chin, they were arranged in tortuous curves. Some of the vesicles were of considerable size. The skin was rough and thickened, and here and there upon the face were scattered papules and pustules. Locally, I directed the following lotion to be used:

℞. Europhen, ʒij.
Glycerini, ℥ij.
Spir. odorati q. s. ad., ℥j.
M. Sig. For external use.

By the persistent employment of the measures recommended, the papules gradually retroceded, the pustules disappeared and the capillary injection in great measure subsided. Altogether the improvement was gratifying alike to physician and patient.

In several cases of facial erysipelas notable amelioration attended the use of an ointment containing from 10 to 20 grs. of europhen to the ounce. The smarting and burning was soon relieved, the swelling diminished and the eruption ceased to spread. The absence of offensive odor is an undoubted advantage which this substance possesses over ichthyol, which has of late been highly recommended and widely used as a topical agent in the treatment of erysipelas. In dermatitis caused by contact with rhus toxicodendron, the application of an ointment beginning with 10 grs. and gradually increased to 1 drachm of europhen is well adapted to serve as a dusting powder upon the surface, after the vesicles have been ruptured. I made use of this remedy, likewise, in several cases of herpes zoster which came under my care. The pain, or at least, the distressing burning and smarting sensations produced by the lesions of zona, are generally mitigated by the use of a dry powder. It is difficult, however, to keep the lesions covered, and for this reason, the slight stickiness of the europhen powder, enabling it to cling closely to the surface upon which it is placed, renders it an excellent medicament in herpes zoster when situated, as it so often is, upon the side of the chest. In the form of a powder, I have also found it of advantage in seborrhœa oleosa. In this condition, I have directed my patients to wash the affected region, before going to bed, with a lukewarm solution of chamomile or boro-glyceride soap, and after thoroughly drying the skin, to cover the surface thoroughly with powdered europhen. The result has been quite satisfactory. The powder remains in place, absorbs the greasy discharge and exerts a tonic and corrective effect upon the affected glands. The simultaneous internal exhibition of the tincture of hoang-nan in the dose of 15 to 30 drops, three times a day, will coöperate in bringing about a cure.

An ointment of europhen appeared to be of assistance in a case of alopecia circumscripta. The surface was painful, long and deep fissures had formed, from which issued a blood-stained serum, vesicles and fissures also existed between the toes. The patient was teased with constant itching, and locomotion was impossible. The treatment adopted was the dusting of europhen-aristol powder between the inter-digital spaces, and the application to the plantar surface of an unguent containing from 1 to 2 drachms of the same powder to the ounce of rose water ointment. The pain and itching soon began to decrease and the fissures to heal. In the course of a week, the patient could endure shoes, and a few days later he was able to go to his place of business. At the end of eight weeks he returned, free from the least trace of eczema. A distant rheumatic diathesis was present in this case, and an internal treatment was addressed to this underlying condition.

A woman, aged 37 years, sought my advice on account of a psoriasis from which she had suffered since girlhood. Patches were to be seen upon various parts of the body. At times the condition would improve, either as a result of medication or spontaneously, the disease would remain quiescent, but after an interval of uncertain periods, an exacerbation would occur. It was during one of these relapses that I first saw the patient. Small patches were interspersed with large oval areas, upon which the characteristic grayish scales were seated. Here and there patches had coalesced, giving rise to fantastically shaped lesions. In some places the scales had become detached, and a thickened, reddened and slightly elevated surface was exposed. The case, in fact, presented a typical picture of psoriasis. A uric acid diathesis was evidently present in this instance, and probably accounts for the inveteracy of the malady. To the constitutional condition an appropriate therapy, which will not here be discussed, was given, while the local medication consisted in the application of a europhen-aristol ointment, the scales having been previously, as far as possible, removed by the usual methods. The ointment was at first made in the proportion of 1 drachm to the ounce of fat, but the strength was gradually raised to 3 drachms. The local measures obviously exerted a favorable influence upon the lesions. The amount of infiltration was markedly lessened, and she was dismissed with directions to continue the use of the ointment at any time that redness appeared. Aristol I had found beneficial in psoriasis, but the europhen-aristol seemed to produce a more decided as well as a more rapid effect.

In syphilis, my experience with europhen and aristol has been principally confined to the open lesions of the late secondary period. Upon ulcers and upon syphilitic rupia, after the latter had been cleared of its accumulated crusts, both the europhen powder alone and the mixture with aristol stimulated the work of repair. I have every reason to regard them as valuable adjuncts to the constitutional treatment. Upon ulcers, often of considerable size, found upon the limbs in late syphilis, especially in those patients who lead dissipated lives, the mixed powder was of advantage. Chancres, chancroids and open buboes are also benefited by the same application.

In the foregoing summary of cases in which europhen has been employed with advantage, the aim has been to record the facts which I have personally observed. The cases briefly glanced at have been selected from a number as being suitable tests of the power of europhen. The solubility of europhen in olive oil renders it well adapted for injection into pus cavities, sinuses and fistulæ. The freedom from offensive odor is a point in its favor. An excellent property of europhen is that it will not harden into compact cakes upon the surface to which it is applied. As an antiseptic dressing, europhen is of value, and the absence of toxicity is another point in its favor. The harmlessness and not unpleasant smell commend this substance in the surgical affections of children and in gynecological practice. That the mixture of europhen and aristol adds something to the efficiency of each, is shown by a case of epithelioma, in which first one and then the other substance were used alone without effecting much benefit, while the mixed products speedily instituted a course of improvement. In some patients the powder acts more beneficially, while in others an ointment is productive of more favorable results. It may be necessary to increase or decrease the strength of the ointment according to the circumstances of the case. I have generally found that a proportion of 1 drachm of europhen to the ounce of excipient makes an efficacious ointment.

A FEW NOTES ON THE MECHANICAL THERAPEUTICS OF OSSEOUS AND MEDULLARY LESIONS OF THE SPINE.

Read by title in the Section of Practice of Medicine at the Forty-third annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY THOMAS H. MANLEY, A.M., M.D.,
OF NEW YORK.

Perhaps in no department of medical science during the latter half of the present century has there been any greater, or as great advance, as in that which embraces within its scope the relief or permanent cure of physical infirmities by mechanical measures. The enormous progress in modernly applied physics, has completely revolutionized pathology, and rendered in many instances, precise accuracy in the diagnosis of disease possible. In nothing, however, have the practical, beneficent influences of these advances been so conspicuous or happily appreciated as in the treatment of disease.

Very naturally, we Americans feel a just pride in the share which members of our profession have contributed; for, although this must go into history as the greatest inventive century that the world has ever witnessed, it must likewise be conceded by the impartial historian, that Americans have, in this direction, occupied the foremost rank, and given to posterity such discoveries and inventions as will endure as long as time itself.

Little time was lost in utilizing and appropriating those principles of mechanics, in the surgical art, which were first mainly limited to the arts and industries. In fact, to-day one can scarcely conceive how it is possible, for the art of mechanical therapeutics to be much further extended. Thus, we thought, twenty years ago, too; and yet, since then we have been time and again, amazed and confounded with fresh proofs, that human ingenuity is but yet in its infancy; never have those of us,of a mechanical bent, ever had a wider field or a more promising future for an ample reward, than to-day.

This has very recently been incontestibly demonstrated, in the immense improvement in the management of spinal lesions, which totally invalided, deformed, or crippled many in former times, but which now, if treated early and properly, by modern orthopædic appliances may, in the majority of cases, recover, with full restoration of function, and little or no deformity.

In order, however, to effectually utilize mechanical appliances in spinal affections, we must have a clear and definite knowledge of the condition which we propose to treat, and the manner in which our therapy is to be utilized, with a view of accomplishing the greatest good and inflicting a minimum of injury.

The pathological conditions of the spine, in which orthopædic instrumentation may serve a useful purpose, may be divided into classes.

The first, is that in which local disease arises from constitutional causes.

The second, is when such lesion follows a traumatism.

The third, when the spinal infirmity occurs from a combination of both the above, as when one predisposed to rachidian disease, suffers a slight or severe injury anywhere over the back.

They may be further sub-divided into lesions (*a*) in which the elements of the cord above are involved, or those mainly limited to the bony column, the cord suffering only consecutively, (*b*) acute and chronic maladies. This division might be continued *ad infinitum*, for the subject is a very large one; but for the purposes necessary to a simple elucidation of our subject at the present, these headings will answer.

In acute spinal meningitis or spinal myelitis, evincing a short course, the back is rigidly fixed by muscular spasm and moves only when convulsive discharges are directed outward.

With this class, exclusive of securing a firm, yet comfortable, resting surface, little good will be derived, from any adjustment appliance.

With those chronic spinal affections of either the cord or bony canal, mechanical appliances, properly utilized in point of efficacy, can be superceded by nothing. This is especially true of the bony skeleton.

But with many, Pott's disease is so insiduous in its development, that the first definite indication of its existence we have is a deformity. Now, on inspection we will notice that the falling in, aching or twisting of the vertebral column, can in any case be readily explained by physical laws. We will observe an invariable shifting of the center of gravity with a compensatory distortion and hypertrophy, of those vertebræ above and below the diseased centre; and of the ribs and sternum as well.

The objects in view in the treatment of what has been designated Pott's disease, *i. e.*, disease of the bones, cartilages and ligaments of the spine, are, 1. To arrest the disease if it has not already made much headway; and 2, to limit deformity. Many methods have been employed to attain these ends. It is unnecessary to say, that in any case hygienic, constitutional and medicinal treatment should go hand in hand with orthopædic appliances. When the early onset of spinal disease is recognizable, it is generally conceded that bodily rest is essential. This holds good, also, in the more advanced cases, in which deformity is already established, and pathological changes are advancing, either slowly or rapidly; and in which, perchance, paresis or paralysis of the upper or lower extremities, or both, announce pressure on the cord, within the canal. In this class then, the question is how shall the necessary rest be best atttained, without, while instituting it, inflicting greater damage to the economy, than if nothing whatever had been undertaken? In answering this question, it is needless to say, that we must under all circumstances be influenced by the surroundings of the patient, his age, the condition of his general health, the precise nature, location, and extent of the malady, which we commence to treat. Before we undertake to describe the various ways, through which limitation of movement can be best effected, and that *rest* secured, which authors attach so much importance to, it is well, that we have a clear interpretation on, or a definition of, what is meant by the term, *rest*.

If we were to understand by it, that the word was synonymous with immobilization, it would be quite a simple matter to immobilize the spine. It is clear, however, to anyone, on very slight reflection, that this sort of fixation, must necessarily entail the employment of braces, stays, and binders, thereby securing constant, uninterrupted pressure, in consequence of which, we must have, through its effect on the soft parts, on the vessels and nerve-trunks, and through cessation of muscular movement, great physical discomfort, a serious interference with nutritive and regenerative processes, and consequent arrest of bodily growth. This indeed, is just what does occur in every case of spinal disease in which its mechanical treatment is abused or misdirected. Absolute immobilization then, means every time, if it be continued long enough (and spinal disease is always a chronic, tedious malady), degeneration of tissue and destruction of function.

Rest, then, must not be comfounded with immobilization. *Rest* in a physiological and surgical sense, means recuperation and restoration, and nothing more. The placing of the parts, the spinal column of bones, or the fractured bone of a limb, or other part of the body, in such a position, or under such conditions, as will aid the regenerative powers, in most promptly regaining their full, functional strength, is *rest*, in its broad and general sense. Limited fixation and interrupted motion are not incompatible with *physiological* rest. On the contrary,-as was pointed out by Prof. Chiene in his justly celebrated address, before the British Medical Association, in 1891, that the broken rib, which never rests in the living body, unites more quickly than any other bone; and, in any fracture he said, he believed properly applied massage, fixation and interrupted pressure rather forced early union than otherwise. Perhaps it would be more comprehensive, if the word *support* were adopted rather than rest; for the latter implies that the spine has been over-strained, overworked, or over-exercised, when nothing is further from the fact. But that it has been damaged by accident or disease, has been weakened, in other words, it goes without saying; then it needs, not rest, but *support*. How this support can be most economically and effectively supplied in each given case, is what particularly concerns us on the present occasion.

In every instance, in the acute stages of spinal disease, or even that phase of it pursuing a chronic course, unless the patients were within a convenient distance of some institution, for free treatment of spinal diseases, in which they will come under the direct observation of experienced surgeons, or they have no means to secure skilled services at home, it will be well to let them spend a considerable share of their time in bed, lying on the back, or either side, in such a position, as will secure as much comfort as possible. The main objection to this line of treatment, is the necessary confinement within doors, want of bodily exercise and the tendency of the patient to so bow the spine, as to greatly aggravate the angular curvature.

Manifold and varied have been the apparatuses devised which would obviate the necessity of this bodily inactivity, and yet permit the patient free use of the limbs with out-door exercise, while supplying ample support to the swaying spinal column. Thoracic-supporters, wire corsets, head rests, steel hooped braces and other appliances almost without number, have from time to time, been selected. But, there were many objections against the use of a greater part of them. They were expensive; they were liable to get out of order; and with the growing child, needed occasional renewal. Independent of these undesirable features, connected with them, if imperfectly constructed, or not properly applied, they often so chafed and irritated the patient, that they had to be thrown aside altogether. It is quite a simple matter, when disease is limited to the cervical vertebra, to lift the weight of the head, off its weakened support without resorting to any one complicated apparatus; but when the vertebral bodies commence to fall inward in the dorsal or lumbar regions, to so apply an adjustment, as will afford ample steadiness and quiet without interfering with respiration, or causing such pressure on the great spinal muscles as will induce a wasting and weakening of them, when the osseous lesion is wholly recovered from, is a difficult problem to solve. Still very much has, of late years, been accomplished in the way of surmounting this difficulty. It is important in the mechanical treatment of spinal disease to bear in mind the fact that when once well established, it is an affliction which runs through years, that it is, however, limited in its course; and finally that it terminates in an anchylosis, or osseous fusion of the affected vertebræ, thereby, forever destroying the elasticity, pliancy and strength of the trunk. Accordingly, in every instance, we must be prepared to deal with a case requiring a long period for treatment; and that our appliances may not, by too long continuance, or want of modification in their construction, do harm to one patient, they must be changed or wholly discontinued when a cure has been finally attained, much depending always, on the thoroughness of the cure, the degree of deformity resulting. In cases of violent traumatisms of the spine, implicating the bone and spinal marrow as a primary measure, I have never had occasion to employ any sort of apparatus or adjustment, except in two cases of fracture in the cervical region. In neither of them was it satisfactory. With the adult who has sustained a very violent concussion of the spine, with or without fracture, it is seldom that the internal organs escape Anyway, there is always more or less extensive bruising of the body. With this class, it is a simple matter to secure the necessary rest to the crushed parts, by placing the body in the prone position, and adding supports in such numbers and situations as may be indicated. The majority of these go on to mortal termination, within the first week. Clearly, it would be immaterial to fix the spine in any sort of an adjustment, when we have indisputable evidence of serious kidney disorganization, or in the presence of such symptoms as would render the immediate prognosis doubtful. Should those cases of spinal traumation pass through the first week safely, and indications of the recovery of the bodily strength are present, then we may consider the propriety of fixing the body in a mechanical adjustment, or introducing such measures as give the greatest comfort and best prospects of recovery.

Our first concern, should be the bed of our patient. It should be narrow, but long, so that in handling him, he will be in a position most convenient of access. The bed should be long, to allow for extension, and a free space at the end of the head and feet. In every case there should be a rope to extend from a staple in the ceiling, with a bar attachment, for the patient to exercise his arms, and as strength returns, to shift his position. The mattress should be of a firm consistence of straw, husk or hair. The bed should have no springs.

When our patient is in bed, little or no good can come from any direct sort of adjustment to the back. It is already amply supported by a firm, comfortable surface underneath and on each side, and a cool comfortable packing can be easily extemporized in every case, in order to prevent a lateral sliding or undue inclination in any one direction. The cervical end of the spine, however, may require a special adjustment if the effects of the traumatism are located here.

In my own cases of injury in this region which went on to recovery, broad, lateral traction, extending down over the ears, passing under the chin, served a most satisfactory purpose.

In cases of fracture of the dorsal vertebra, without considerable displacement, some resort to enveloping the lower thorax in a plastic material, while others prefer extension of the spine, though, until quite recent times, no mechanical adjustment of any description was employed. It has long been a disputed question whether or not the spinal column is capable of mechanical extension by weights acting on the lower extremities, while the body lies in the prone attitude. Assuming that effective extension on the back is possible, yet the confined posture of the body, with the tendency to bedsores, and difficulties in the way of supplying the demands of nature, render it an undesirable means of relief; particularly when others more efficacious are readily accessible. In my own hospital service, with a considerable experience in the management of spinal traumatism, when the lesion has been limited to the osseous elements, extension or counter-extension has rarely been applicable.

In many we will observe, in pathological conditions of the spine of a constitutional or traumatic origin, an association of morbid processes which involve, simultaneously, the medullary and osseous elements; varying phases of paralysis being observed, while full mobility of the spine may be temporarily or permanently in abeyance. Lastly, there is another, the rarest group, in which there is no evidence of bone disease, the pathological lesions affecting the cellular elements, or membranes of the cord, in either one or both lateral divisions of the column, and occupying varying areas; hence in one we will meet with monoplegia, another paraplegia, and in another motion is absent, but sensation is present. In fact, in those myopathies of an eccentric or spinal dependence, they assume every sort of simple and complex phase, from the bedridden state, to a general or local ataxic condition of muscular movement.

MECHANICAL APPLIANCES.

The mechanical apparatus which may be utilized with the greatest advantage, in the three divisions of spinal lesions here defined, may be divided into two classes, viz.: those which are fixed and those which are movable, or portable. The one entails a more or less fixed position of the spine, while the other permits of free movement and is intermittent in its action. It would be useless to go back into the early history of the healing art, to trace the origin of mechanical supports in spinal maladies: suffice it to say, that they have been employed, in a crude form, since very remotest ages, for at present we are chiefly concerned with the advances of our own times.

The fixed apparatus is a brace, calculated to lift and carry the superincumbent weight from the seat of disease. They are manufactured from every conceivable pattern and material. It was not until Prof. Lewis A. Sayre utilized the plastic and yet powerful properties of plaster of Paris that an ideal material was discovered, which is adaptable to a very wide range of spinal maladies. The cheapness of this material leaves it within the reach of the surgeon, and there is no deformity which it cannot be adapted to. But, there are certain, definite principles which must be observed in its application and use, or it will do more evil than good. It must be remembered that the plaster jacket, so-called, is applied principally for the double purpose of maintaining counter-extension while it supports the yielding spine. With the growing child it must be frequently changed, in order not to interfere with growth or cause muscular atrophy.

In the acute stage of Pott's disease, Sayre's plaster jacket stands almost without a rival. In the paretic or paralytic, in which there is a tendency to a sort of "tumbling-in" of the lower dorsal, or upper lumbar vertebræ, in the adult, it is a veritable godsend to those unable to provide expensive apparatuses, or those who cannot wear them.

The cases in which the Sayre-jacket serves the most useful purpose, are those, in whom the disease is chiefly osseous, for I am not aware, that it has been recommended extensively in conditions of the spine of a purely neurotic type.

It has been alleged by not a few, that the great utility of Sayre's jacket is derived rather from the body suspension and spinal extension, in its adjustment, than from the jacket itself. And acting on this assumption, neurologists have applied suspension in tabes-dorsalis and other affections of the medulla-spinalis, with varying results, since Sayre's invention. The principal objection to the plaster jacket is, that its action is constant; there is no "let up," so to speak, but the pressure which it induces is continuous, so that there is liability to myopathic, degenerative changes, with erosions and ulcerations at osseous points not imbedded in muscular or adipose tissue. This has in part been lately obviated by splitting and lacing the jacket anteriorly, so that pressure can be more equably adjusted.

Moreover, there are cases in which the gypsum dressings are not applicable, or cannot be comfortably worn, besides many in which it fulfils but one indication, in which it is obvious that something else is desirable, something which permits of interrupted, full extension of the spine in the upright position, without continued lateral pressure, so as to allow of massage of the dorsal muscles and free, unrestrained action of the hands and arms, when these members are not palsied.

I can in no manner describe the class which I refer to, better than by citing a case:

The patient was a young woman, who was sent into my service at the Harlem Hospital of New York, early in the summer of 1891. She gave a history of having injured the spine by a fall some months before, from which time, she was completely paraplegic, and paralyzed from the mid-dorsal region of the body downwards, although control of the anal and vesical sphincters was maintained. The consideration of this case from a forensic point of view I have fully dwelt on in a brochure presented elsewhere.[1]

She was considerably emaciated, with a poor appetite, and was in a melancholy state of mind. The plaster jacket had been applied before she came in, but effected no benefit, besides caused so much discomfort, that it had to be laid aside. It was apparent that this case, which presented well marked indications of disease of the vertebræ, with pressure on the cord, required some sort of a mechanical appliance to either supplement the jacket or substitute it; which would permit of vertical extension of the spine, ample support of the body, and free muscular action in the parts not involved. At about the time she was admitted, while on my way to Washington to attend the meeting of the American Medical Association, I met on the night train Dr. Meigs Case, of Otsego Co., N. Y. He described his portable carriage, known as "the Meigs Case Spinal Apparatus," for spinal infirmities, and advised me to try it on this patient. Immediately on my return, some kind lady friends, on my recommendation, purchased of the Pomeroy Truss Co. one of these carriages. At first she was so utterly helpless and limp, that in adjusting her in the spinal apparatus, it was like swinging a corpse; but after a few persevering trials she commenced to gain confidence, and could assist us with her arms. After one month, full sensation returned in the extremities, this was followed by occasional involuntary spasms of the lower spinal and femoral muscles. After three months, she could stand and steady her body by firmly holding the side-bars with her hands. After six months, she was able to lift the feet and take five steps without any assistance. From this time onward her progress was rapid. At first walking with crutches, then with a cane, and finally, when she left the hospital, nine months after admission, going about where she pleased, without any support of any kind, except the corset.

Simultaneously with the commencement of the use of Dr. Case's spinal apparatus, her general strength commenced to improve, the appetite was better and constipation disappeared. Shortly after improvement was well marked, being desirous of sitting up, another Sayre jacket was adjusted, which she wore with great comfort until she left us.

From my experience with this case, and a study of the mechanical principles on which the Meigs Case spinal apparatus operates, I feel amply justified in recommending it in a very large class of spinal diseases, and in maladies of the spinal cord which present symptoms of paralysis or incoördination, in an early stage of life. It fulfils, in a larger measure than any other apparatus, the indications for mechanical therapeutics of the spine, in providing simultaneously bodily support, vertical extension and free muscular movement. I am confident that a better acquaintance with the many purposes which this valuable contrivance serves, and a familiarity with its use, will commend it to every practitioner who is desirous of securing for his patients such facilities as will favor the rapid and complete restoration of spinal function.

---

[1] Annual Meeting of Association of Railway Surgeons at Old Point Comfort, Va., May 25, 1892. "Diagnosis and Prognosis in Spinal Lesions."

When all symptoms of paralysis have disappeared, and only weakness remains, then, with those unable to provide expensive, complicated braces, the employment of the Sayre jacket is indicated. It may be made light or heavy as required, and be renewed or dispensed with, as conditions indicate. In all cases of spinal infirmities requiring any sort of extension or support, the patient's bodily comfort is enhanced, besides, the state of the muscles and internal organs are all benefited by massage, judiciously applied.

EPILEPSY.

Read by title in the Section of Practice of Medicine, at the Forty-third Annual meeting of the American Medical Association, held at Detroit, June, 1892.

BY M. M. LEAHY, M.D.,

OF CHICAGO, ILL.

Admitting that from the time of Aristotle, when a knowledge of the structure and functions of the human body first began to be cultivated systematically, down to the present day the demonstrator of morbid anatomy has not lived who can point with unerring finger to the cause of epilepsy; admitting, too, that of more than eight millions of the world's people, whom statistics prove to be epileptics, perhaps less than one third are curable; yet we claim that in our thirty years' experience, both in Europe and in the United States, we have not been without some measure of success in the treatment of epileptics who continue to report themselves free from fits.

In response to a request for a chapter from our own experience in the treatment of epilepsy, leaving its etiology, pathology and history to the many able medical writers of the day, we purpose giving a brief history of a few selected typical cases and if this should prove helpful to one student or inexperienced young physician the mission of this paper will have been accomplished.

We have been asked our method of diagnosis and in reply would say, we use our educated senses.

It was our fortune throughout our entire European course of medical training to be a special student under a preceptor who, while he possessed one of the finest medical libraries in the kingdom, regarded all book knowledge as secondary to education of eye, ear and fingers. The student was put in a hospital with the understanding that no physician ever knew a thing that he could not see, hear or feel for himself. His text-books were the patient and the cadaver; there he staid and there he wrought under the most rigid task masters until he could tell almost instinctively, not only the ailment, but the treatment that should be used in battling with the disease. So while we have no wish to depreciate the many excellent instruments used as aids in detecting morbid conditions of the body, our own educated eye, ear and finger tips serve us with a fidelity that few manufactured instruments can equal or surpass.

It is said, if you place before a certain cultured lady, blind from her birth, a gorgeously embroidered cloth, that by passing lightly over it with the delicate tips of her educated fingers she can describe, not only the texture of the materials but every shade and tint of color used.

Now, one need not be born blind to detect the soft, mellow skin of phthisis or the dry, scaly skin of syphilis. Neither need he be bereft of other senses to hear an abnormal vesicular murmur or to read the history which every pain records upon the human countenance.

It is, then, with every sense on the alert, that we search for the break or obstruction in the physical economy of the epileptic; and when found, our entire energy is directed to the repair of the break or the removal of the obstruction.

Since no two constitutions require precisely the same medical and hygienic treatment we pay the greatest respect to the several idiosyncrasies of our patients. In fact the therapeutist has not lived who has dared pronounce upon the best "fit remedy" that ever issued from the door of a chemist's laboratory as even approaching infallibility, and the man who advertises a specific dose of a special nostrum as a cure for epileptic fits regardless of temperament or condition of the patient must be a fraud or a fool.

We have been asked our judgment with reference to the probability of cure in a case of genuine epilepsy. In our own practice we have found that if the predisposing cause be compression of the brain or lesion of the spinal cord, the chances are, at least one hundred to one, that the former will be followed by idiocy or softening of the brain and the latter by paralysis, both terminating fatally.

If the patient be the offspring of scrofulous, intemperate, phthisical, syphilitic or epileptic parents we may give relief for months and even years at a time, but the chances are against a permanent cure.

If, however, the predisposing cause be a simple disturbance of some part of the alimentary canal, the liver or the kidneys, an irritation of the pneumogastric nerve, the chances are decidedly in favor of a permanent cure.

The history of the following selected cases may serve to explain our general plan of treatment:

About five years ago while conversing with a friend in one of the public buildings of Boston, Massachusetts, we observed an employee, a finely built, robust, young man approaching. Just before he reached us he uttered a harsh scream and fell, bruising his face upon the stone where we stood. Instantly placing him upon his back, with a coat for a pillow, and a block of cork between his teeth, and loosening his neck-wear we watched the progress of the fit. With eyes fixed, pupils dilated, head drawn down toward the left shoulder, face and eyes directed toward the right, breathing and sensibility suspended, left arm and leg extended and twisted, left foot arched, fingers and toes flexed, he was as stiff as a board for nearly a minute. Then began exaggerated muscular relaxations and contractions of the entire body. The breathing now resumed was loud and jerky, the color changed from deathly pale to dark purple while the veins of the neck became much distended. Of a sudden every muscle was forcibly stretched to its full length and instantly relaxed and the patient gave a long, loud sigh, thus ending a fit of not more than three minutes duration. This was followed by a lethargic sleep and a dull, confused awakening, lasting but a few moments, during and after which we made a careful diagnosis of his general physical condition. We discovered ecchymoses on the face and neck, a stomach distended with gas and undigested food, a gorged liver, the lower bowel distended with gas and feces, a clear case of *le grand mal*, induced by irritation of the pneunogastric nerve. As he had the strength to bear rather heroic treatment, we gave both emetic and cathartic to clear out the alimentary canal. We stimulated the liver, kidneys and lymphatics, opening up nature's channels, giving her a chance to rid herself of all morbid matter. We then gave bromides in an infusion of belladonna leaves, commencing with a small dose and increasing the quantity until we reached the maximum dose his constitution would bear. We gave a hydragogue to prevent venous congestion, using

entire absence of jaundice—we may safely predict the presence of a calculus in the gall bladder.

Gall stones may remain in the gall bladder for an indefinite time without the least pain; at other times there may be present the most dangerous symptoms such as I have described, without the slightest trace of jaundice. *When impacted in the cystic duct*, then the suffering becomes intense, and so long as it remains, although no bile can enter into the gall bladder or escape from it, yet it offers no obstacle to the direct flow of the biliary secretion from the liver into the intestine. So long as this impaction remains the patient is in the condition of a person upon whom cholecystectomy has been performed.

The office of the gall bladder is to act as a diverticulum and a receptacle, and contains the excess of bile secreted during the intervals of digestion; aside from this it is non-essential; it is absent in many instances, in several animals, such as the horse, the deer, the elephant and in many birds, such as the ostrich and the parrot.

Budd says the effects of the closure of the cystic duct, on digestion and the general health, are much less serious than might be expected, and are sometimes of very little import. Dr. Alexander Simpson report a case in the *Edinburg Medical Jaurnal*—of a child in whom no trace of a gall bladder was found at the autopsy.

How can we account for the presence of pain when a calculus is impacted in the cystic duct? The solution readily presents itself, if we remember that the gall bladder is provided with a muscle, and that it must contract with increased force to overcome the resistance offered by the calculus fixed in the cystic duct, just as the urinary bladder contracts with increased energy when a calculus is arrested in the canal of the urethra, or the ureter contracts when a renal calculus travels along it to the bladder.

What is the condition of the gall bladder when digestion is going on in the stomach? It is full of bile and it empties itself by a powerful contraction while the digested food is passing through the duodenum.

No one perhaps stated the cause of hepatic colic more clearly during digestion than Bartholow. He asserts that common observation shows that the symptoms of hepatic colic usually declare themselves in two or three hours after a meal. At that time when the presence of the chyme in the duodenum solicits the flow of bile, the gall bladder contracts on its contents in direct ratio to the amount of bile present, and with the gush of fluid the concretion is whirled into the duct.

The muscular tissue having undergone hypertrophy—owing to the efforts to overcome the obstruction dependent upon the impacted calculus, the paroxysms of pain are more likely to occur at this time than any other, and the persistent and unyielding obstruction will produce the distension and enlargement of the gall-bladder already alluded to. There is yet another difficult problem to solve—why is it that in some cases we have distension augmented until the viscus descends even to the iliac crest, containing pints of fluid, while in other cases, a much less frequent occurrence, we find atrophy of the gall bladder contracting and embracing the calculus. Rokitansky believes that its obliteration is frequently consequent upon inflammation.

The enlargement of the gall bladder is largely due to the presence of the mucus secretion from the lining membrane of the gall bladder itself.

There came to my office in the month of December 1890, Mrs. C., aged 34, from Colorado. She complained of pain in in the right hypochondriac region and shoulder; it was increased by violent exercise. There was present also headache and diarrhœa; she was pale and emaciated. She described her sufferings as follows: excruciating pain lasting several hours, usually occurring two hours after meals. The relief was as sudden as the attack. After the paroxysms of pain the tenderness was felt for several days. Not the slightest evidence of jaundice was ever present. There was nothing abnormal in the urine. Upon examining the abdomen I found a tumor to the right of the umbilicus and with its lower part upon the brim of the pelvis. Its shape was pyroform. In size as large as the largest pine-apple. It was free from tenderness. The treatment had been medical only; numerous remedies were tried without affording her any relief. She came to consult me with reference to the possibility of a surgical procedure. I stated to her my diagnosis: that her trouble resulted from calculi in the gall bladder with possibly obstruction of the cystic duct causing distension, that the painful paroxysmal aggravations were due to this cause, and if left alone my prognosis was that a fatal result would inevitably follow. She consented to an operation, and on Dec. 11, 1890, at the St. Joseph Hospital, after observing minutely the special antiseptic precautions which precede laparotomy, general anæsthesia was induced by the inhalation of ether; afterwards the patient was placed upon the table suitably prepared, and the abdomen cleansed. An incision four inches in length was made from the tip of the cartilage of the tenth rib down towards the fundus of the tumor. On reaching the peritoneum it was picked up by catch forceps, and the line of incision continued with scissors. An index finger was introduced to feel for the gall bladder. It was easily discovered, and I was enabled to bring up the fundus with the fingers without the use of the forceps; and lodged in the wound. Its size was diminished by aspirating. Sponges were carefully packed, to receive whatever fluid might escape during this part of the operation. I used catch forceps, seized the fundus at the upper and lower portions, and incised it, inserting my finger to feel if any calculi were present; discovered there were, and removed six of them impacted in the cystic duct. They were removed by using a small scoop and forcep. The gall bladder was now drawn freely into the wound, and the edges of the abdominal wound and the gall bladder were closely kept together by an assistant. The edges of the wound in the gall bladder were sutured by a continuous thread of carbolized silk; this done the bladder was washed out with warm water and a careful search made for calculi; none were found, after which a drainage tube was inserted, and iodoform dressing applied.

The fluid was glairy mucus; the evidence of bile wanting. This, in connection with the quantity—several pints—clearly indicated that the obstruction had existed a long time. I allowed the drainage tube to remain until the 24th day of December. No bile escaped from the wound during or after the operation. A fistulous opening remained and continued to discharge mucus for several months. All my efforts to close it were only partially successful, for if closed for a week or ten days, she complained of fulness and pain over the region of the gall bladder; but when a discharge took place it was followed by relief. At one time when the closure existed longer than usual she concluded to visit Buffalo in the month of April to consult the eminent surgeon Dr. Park. He, after an examination, advised her to return and renew the opening first made, and pack the gall bladder with iodoform gauze. I followed his suggestions but failed to obliterate the cavity. I now attempted by various methods to change the interior of the gall bladder by using injections of compound tincture of iodine, tanin, gallic acid and nitrate of silver. I thus reduced the cavity until it held only a half drachm. It seemed almost closed when she left me for her home. Her general health was marvelously improved; she was free of pain unconfined; exercised freely without exciting any of the symptoms that previously distressed her; even with her improvement I was compelled to listen daily to her complaint concerning the slight stain upon the dressing; but I consoled myself that the varying quality of mentalization is due to the fluctuations in the activity of the hepatic function, and that many a dark ecclesiastical dogma about man and God, have had their origin in the cystic duct.

I firmly believe after reading the lamentations of iodide of potassium or Fowler's solution upon any appearance of bromidism. When last heard from, a few months ago, there had been no return of the fits.

A young lady of Augusta, Maine, may serve as another typical case. The approach of her attack was indicated by a fancy that she heard the most enchanting music, and in her effort to catch the tune which seemed very familiar she lost consciousness in an epileptic fit. Being a sufferer from anæmia our aim was to build up the system, mentally and physically. We prescribed whites of fresh raw eggs, beaten in plenty of fresh milk to make blood, baths and massage to stimulate the capillaries,-rubbing the entire body with good olive oil once or twice a week. gentle out-of-door exercise and entertainment adapted to her taste and capacity. We then gave bromide of lithium and tonics with gratifying success.

We had, not long ago, a patient whose severe epileptic attacks were followed by mental derangement. At times he would hunt in the bed, under the carpet, in the garret and in the cellar for something he fancied he had lost. At other times he would break and destroy everything that came within his reach, even attempting to kill those he met. In such cases we have observed that bromides are decidedly harmful, tending to increase the irritation. In this instance we found the fluid extract of water hemlock alternate with borax, ergot and phosphates, very efficacious in the way of soothing the patient and checking the convulsions. In the course of a few months he died of softening of the brain.

While in charge of a dispensary in Kinmare, county of Kerry, Ireland, a patient, whose case resisted all remedies, died in *status epilepticus*. The autopsy pointed directly to *phthisis renalis* as the predisposing cause.

At the same time we had under our care a young girl afflicted with violent epileptic seizures who was a sufferer from retention of urine. An examination revealed tube-casts and albumen. Our treatment was directed exclusively to the local troubles and when their cure was effected the fits departed and we have never heard of their return.

We have at present under our care a girl aged 10, whose father, an epileptic, died at forty of softening of the brain. Naturally of tractable temper, she took spells, when for days she was irritable, morose and stubborn, culminating in an attack in which the face paled, the pupils dilated, the eyes became fixed and the muscles rigid, lasting but a few seconds. She did not fall and lost consciousness for a few seconds only, but was stupid and forgetful for several days before returning to her normal condition. As is common among epileptics she is a gourmand. We purged her thoroughly, afterwards administering fluid extract of belladonna, 10 drops daily. She has had no return of the fits for five months; but, being inherited, her case must needs be closely watched, especially as she is likely at any time to bring on intestinal irritation by over-eating.

A Chicago boy, aged 9, had violent seizures of *le grand mal* for which we treated him with bromides in an infusion of belladonna leaves without a return of the fits for one year, when not we, but his parents pronounced him cured. All went well until he had an attack of pneumonia after which he become a victim of *le petit mal*. Many times a day he caught hold of his mother with both hands and with violent grimaces uttered a hoarse cry as if in great pain. The attacks lasted but a few seconds after which he seemed dazed and entirely unconscious of what had happened. He had constant and extreme nausea. We gave as strong cathartic and emetic doses as his debilitated constitution would bear, with the result of bringing away from both stomach and bowels an incredible amount of matter having the appearance of strips of sheep skin, with a stench that was almost unendurable. To quiet and soothe we gave sulphate of atropine 1-120 gr. with sulphate of morphia 1-10 gr. and in a few days resumed the bromide and belladonna treatment. There has been no return of the fits since resuming the treatment.

There are a number of other cases illustrative of stages intermediate between *le petit mal* and *le grand mal* in which we are greatly interested; but we refrain from a description feeling that the promised short chapter has already grown sufficiently long.

In conclusion we will say that the greatest obstacle in the way of permanent relief on the part of those who are curable is the unwillingness of the patient and his friends to continue the treatment, medical and hygienic, sufficiently long. After the fits are stopped and the patient looks and feels first rate, both he and his friends seem to regard any effort to induce him to continue treatment as a collusion of doctor and druggist to defraud him of his money.

Before commencing treatment we aim to secure a promise that the patient will continue one, two, or three years as his case may require. Oh, yes, he is ready to promise a five years' trial if we ask it; but four out of five fail to keep a one year promise. The fits return, of course, and the doctor is expected to shoulder the blame.

Is it Utopian to hope that we as honest, earnest physicians whose object is the greatest good to the greatest number of suffering humanity, may, at no distant day succeed in convincing the State at large, of the necessity for special hospitals where all epileptics may be carefully and scientifically treated and where the curable may be kept until they are cured?

OBSTRUCTION OF THE CYSTIC DUCT, WITH A CASE.

Read in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June 7, 1892.

BY W. H. MYERS,
OF FT. WAYNE, IND.

I will invite your attention for a few moments to obstruction of the cystic duct, a region only recently invaded by the surgeon ; a subject not alluded to in Mutter's Syllabus of 1883, nor found in Cheyne's of 1892.

That the treatment of hepatic disease remained in the field of medicine until within a recent period is proven by the fact that the surgical treatment of the liver by cholecystotomy was first performed by Dr. Bobbs, of Indianapolis in 1867.

In obstruction of the cystic duct there is occlusion, or stenosis. In the first the closure is complete: in the latter less complete. These conditions are dependent on foreign bodies within the duct, or upon some disease or thickening of the walls, or the presence of pressure from a tumor without. The most common cause is an impacted gall-stone in the cystic duct. If the cystic duct alone is obstructed, the office of the gall-bladder is destroyed; this leads to various changes. The bile in the gall bladder is absorbed and its place is supplied by a glairy fluid of the consistency of mucus or synovia, often so abundant as to fill the gall-bladder, and sometimes greatly distend it; it becomes a thin walled cyst holding several pints. It is now completely cut off and no longer available as a receptacle for bile; its nutrition impaired, changes in structure follow, with the phenomena inflammation and ulceration. These changes are local, for a stone lodged in the cystic duct can by no possibility produce jaundice; its presence will only prevent the bile from passing in or out of the gall bladder.

How are we to know whether or not the cause of obstruction is an impacted gall-stone? The diagnosis is positive when the patient passes a calculus; before this occurs our data are probabilities. If the following symptoms are present in a case—violent pains in the right hypochondrium, shooting through the whole abdomen up to the chest and right shoulder, nausea and vomiting seldom absent, these symtoms occurring at longer or shorter intervals, with an entire absence of jaundice—we may safely predict the presence of a calculus in the gall bladder.

Gall stones *may remain in the* gall bladder for an indefinite time without the least pain; at other times there may be present the most dangerous symptoms such as I have described, without the slightest trace of jaundice. *When impacted in the cystic duct,* then the suffering becomes intense, and so long as it remains, although no bile can enter into the gall bladder or escape from it, yet it offers no obstacle to the direct flow of the biliary secretion from the liver into the intestine. So long as this impaction remains the patient is in the condition of a person upon whom cholecystectomy has been performed.

The office of the gall bladder is to act as a diverticulum and a receptacle, and contains the excess of bile secreted during the intervals of digestion; aside from this it is non-essential; it is absent in many instances, in several animals, such as the horse, the deer, the elephant and in many birds, such as the ostrich and the parrot.

Budd says the effects of the closure of the cystic duct, on digestion and the general health, are much less serious than might be expected, and are sometimes of very little import. Dr. Alexander Simpson report a case in the *Edinburg Medical Jaurnal*—of a child in whom no trace of a gall bladder was found at the autopsy.

How can we account for the presence of pain when a calculus is impacted in the cystic duct? The solution readily presents itself, if we remember that the gall bladder is provided with a muscle, and that it must contract with increased force to overcome the resistance offered by the calculus fixed in the cystic duct, just as the urinary bladder contracts with increased energy when a calculus is arrested in the canal of the urethra, or the ureter contracts when a renal calculus travels along it to the bladder.

What is the condition of the gall bladder when digestion is going on in the stomach? It is full of bile and it empties itself by a powerful contraction while the digested food is passing through the duodenum.

No one perhaps stated the cause of hepatic colic more clearly during digestion than Bartholow. He asserts that common observation shows that the symptoms of hepatic colic usually declare themselves in two or three hours after a meal. At that time when the presence of the chyme in the duodenum solicits the flow of bile, the gall bladder contracts on its contents in direct ratio to the amount of bile present, and with the gush of fluid the concretion is whirled into the duct.

The muscular tissue having undergone hypertrophy—owing to the efforts to overcome the obstruction dependent upon the impacted calculus, the paroxysms of pain are more likely to occur at this time than any other, and the persistent and unyielding obstruction will produce the distension and enlargement of the gall-bladder already alluded to. There is yet another difficult problem to solve—why is it that in some cases we have distension augmented until the viscus descends even to the iliac crest, containing pints of fluid, while in other cases, a much less frequent occurrence, we find atrophy of the gall bladder contracting and embracing the calculus. Rokitansky believes that its obliteration is frequently consequent upon inflammation.

The enlargement of the gall bladder is largely due to the presence of the mucus secretion from the lining membrane of the gall bladder itself.

There came to my office in the month of December 1890, Mrs. C., aged 34, from Colorado. She complained of pain in in the right hypochondriac region and shoulder; it was increased by violent exercise. There was present also headache and diarrhœa; she was pale and emaciated. She described her sufferings as follows: excruciating pain lasting several hours, usually occurring two hours after meals. The relief was as sudden as the attack. After the paroxysms of pain the tenderness was felt for several days. Not the slightest evidence of jaundice was ever present. There was nothing abnormal in the urine. Upon examining the abdomen I found a tumor to the right of the umbilicus and with its lower part upon the brim of the pelvis. Its shape was pyroform. In size as large as the largest pine-apple. It was free from tenderness. The treatment had been medical only; numerous remedies were tried without affording her any relief. She came to consult me with reference to the possibility of a surgical procedure. I stated to her my diagnosis: that her trouble resulted from calculi in the gall bladder with possibly obstruction of the cystic duct causing distension, that the painful paroxysmal aggravations were due to this cause, and if left alone my prognosis was that a fatal result would inevitably follow. She consented to an operation, and on Dec. 11, 1890, at the St. Joseph Hospital, after observing minutely the special antiseptic precautions which precede laparotomy, general anæsthesia was induced by the inhalation of ether; afterwards the patient was placed upon the table suitably prepared, and the abdomen cleansed. An incision four inches in length was made from the tip of the cartilage of the tenth rib down towards the fundus of the tumor. On reaching the peritoneum it was picked up by catch forceps, and the line of incision continued with scissors. An index finger was introduced to feel for the gall bladder. It was easily discovered, and I was enabled to bring up the fundus with the fingers without the use of the forceps; and lodged in the wound. Its size was diminished by aspirating. Sponges were carefully packed, to receive whatever fluid might escape during this part of the operation. I used catch forceps, seized the fundus at the upper and lower portions, and incised it, inserting my finger to feel if any calculi were present; discovered there were, and removed six of them impacted in the cystic duct. They were removed by using a small scoop and forcep. The gall bladder was now drawn freely into the wound, and the edges of the abdominal wound and the gall bladder were closely kept together by an assistant. The edges of the wound in the gall bladder were sutured by a continuous thread of carbolized silk; this done the bladder was washed out with warm water and a careful search made for calculi; none were found, after which a drainage tube was inserted, and iodoform dressing applied.

The fluid was glairy mucus; the evidence of bile wanting. This, in connection with the quantity—several pints—clearly indicated that the obstruction had existed a long time. I allowed the drainage tube to remain until the 24th day of December. No bile escaped from the wound during or after the operation. A fistulous opening remained and continued to discharge mucus for several months. All my efforts to close it were only partially successful, for if closed for a week or ten days, she complained of fulness and pain over the region of the gall bladder; but when a discharge took place it was followed by relief. At one time when the closure existed longer than usual she concluded to visit Buffalo in the month of April to consult the eminent surgeon Dr. Park. He, after an examination, advised her to return and renew the opening first made, and pack the gall bladder with iodoform gauze. I followed his suggestions but failed to obliterate the cavity. I now attempted by various methods to change the interior of the gall bladder by using injections of compound tincture of iodine, tanin, gallic acid and nitrate of silver. I thus reduced the cavity until it held only a half drachm. It seemed almost closed when she left me for her home. Her general health was marvelously improved; she was free of pain unconfined; exercised freely without exciting any of the symptoms that previously distressed her; even with her improvement I was compelled to listen daily to her complaint concerning the slight stain upon the dressing; but I consoled myself that the varying quality of mentalization is due to the fluctuations in the activity of the hepatic function, and that many a dark ecclesiastical dogma about man and God, have had their origin in the cystic duct.

I firmly believe after reading the lamentations of

Jeremiah when he exclaims "My bowels; my bowels," "I am pained, I cannot hold my peace. My liver is poured upon the earth," I believe that he had obstruction of the cystic duct, and that Jonathan Edwards was afflicted with jaundice when he wrote his ghastly sermons on eternal damnation. George Sand thus afflicted exclaims, "Since my disease first appeared, I have had happy years, and when it seized me again, although I was in the condition most favorable to love of life, I felt myself suddenly seized with a desire for eternal repose."

After the digression it remains for me now, only to present for your consideration the question, "whether in cases where the gall bladder is filled with mucus dependent upon continuous obstruction of the cystic duct—it were not better to perform cholecystectomy? I wish here to emphasize the fact that the cystic duct is often closed by adhesive inflammation, and that it remains closed in such cases after the calculi are removed. In support of this view I will quote from Budd, who says, "A gall stone too large to pass through the duct floats with the current of the bile, to its mouth, and becomes firmly lodged there, and generally leads to lasting closure by adhesion beyond the stone, the effect being closure of the cystic duct."

In another case such as the one reported I would ligate the cystic duct at two points, and divide between them, and as the gall bladder has ceased to be a receptacle for bile, I should remove it. We remove the ovaries when they become cystic, also the spleen and the kidney, and why not the gall bladder?

LATE MANIFESTATIONS OF APPENDICITIS AND THEIR TREATMENT.

Read in the Section of Surgery and Anatomy, at the Forty-third annual meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY DUDLEY P. ALLEN, M.D.,

VISITING SURGEON TO LAKESIDE AND CHARITY HOSPITALS, CLEVELAND, O.

The late manifestations of appendicitis are so frequent and so serious that it would seem to me that the discussion by this distinguished body would be of interest and benefit. The question of operation in primary attacks has within recent years received wide consideration at the hands of American surgeons, and the operation has been placed upon a lasting and scientific basis. Witnessing cases which have not thus been operated, together with the serious complications which have succeeded, after apparent recovery from the local disease, I have been further impressed with the correctness of the position which has been taken in favor of early operations. I have recently had an opportunity for conversing upon this subject with a large number of prominent surgeons of Europe, and have repeatedly met the expression that with them in Europe, appendicitis does not seem so serious, nor to demand operation so frequently as has been recommended by American surgeons, and the opinion was expressed that it was safer to leave cases of appendicitis to pursue their natural course without operation or surgical interference.

As I recall the cases of appendicitis which I have seen in consultation both before and since early operation has been advocated, I am strengthened in my opinion that the natural history of the malady, both in its primary attacks and subsequent history, is so serious as fully to warrant the position taken by American surgeons in favor of early operative interference.

For the introduction of this discussion I have selected six cases, each differing from the other, as perhaps the best means of presenting the subject. I have purposely selected as few cases as will serve this purpose.

The first case is one of the most common of those in which repeated slight attacks of appendicitis have ultimately eventuated in one of serious import. The case was A. H., æt. 21, with good family and personal history. He had repeatedly suffered from abdominal pain, which he supposed to be colic. On May 3, 1892, he had a similar attack, and went to his office in the morning but returned home in a few hours. He vomited and the pain continued, but the patient simply laid upon the sofa and did not take to his bed until perhaps thirty hours after the beginning of the attack. His temperature and pulse remained normal. His bowels moved with a saline, on the second day of the attack. On the third day of the attack there was some tympanitis and tenderness upon the right side, but the pain did not become localized in the region of the cæcum until the fourth day, and at that time his pulse was normal and his temperature was 99. On the fifth day the temperature and tympanitis increased slightly, while on the sixth day the evening temperature had reached 102 1-5, and the region was extremely tender. On May 10, the seventh day of the attack I was called to operate on the case by my friend, Dr. Boyd, of Akron, meeting in consultation Dr. Boyd, Drs. Jacobs, Sr. and Jr., and Dr. Hoover. I found the patient's abdomen considerably distended and very tender. There were dulness and resistance in the region of the cæcum. The pulse was 80 and the temperature 100. At 10 A.M., I operated, evacuating perhaps 8 oz. of pus. I found a gangrenous appendix containing a concretion. In the removal of the appendix the abdominal cavity was opened in two places, the presenting intestines were kept thoroughly flooded with water and were subsequently held back by tampons of iodoform gauze. The progress of the case has been satisfactory in every respect. The interesting feature of this case is that the attack of appendicitis which eventuated in a large abscess, seriously threatening the patient's life, did not differ primarily from what he had considered simple attacks of colic, and it is not at all improbable in my mind that the previous attacks of pain had the same origin as the last.

The second case was of Mrs. H. F., æt. 30, a woman of medium size and well nourished. On Sept. 9, she complained of pain in the abdomen, but did not locate it in the right side until the day following. The second night she took a tablespoonful of Carlsbad salts, and had a free evacuation upon the morning of the third day. On the same day she was seen by Dr. Bock, who administered a cathartic and applied fomentations. The temperature previous to the sixth day of the attack did not exceed 101, but afterwards rose gradually until Sept. 20, eleven days after the beginning of the attack when the evening temperature was 104. The patient had had no chill or vomiting, but had had slight nausea. I first saw the patient on Sept. 20, the eleventh day of the attack, and found her very tympanitic, with temperature 105; the abdomen was not tender. On the right side from the cæcum upward toward the ribs was dulness, though there was resonance on deep percussion. The skin was somewhat discolored, due as it was supposed, to external applications. There was an indistinct sense of fluctuation, but all local symptoms were rendered less prominent by reason of great general tympanitis and local tenderness. An examination the following morning under an anæsthetic showed fluctuation to be distinct. On Sept. 21, twelve days after the attack, in the presence of Drs. Carl and Herman Bock, and Dr. Krause, I operated upon the patient. Just previous to the operation temperature was 103½, the pulse was fairly strong, and the bowels had moved several times with a passage of considerable flatus. On dividing the abdominal wall in the region of the cæcum fully two quarts of black ichorous fluid were evacuated, and with it large masses of broken down gangrenous tissue. The peritoneal cavity was not opened. The abscess cavity extended from under the ribs above to Poupart's ligament below. The patient endured the operation well. The same night she was in excellent condition. At 2 A.M., the following morning she told Dr. Bock, who spent the night with her, to go and lie down since she did not need him, and would call him if required. Some time later he noticed that her breathing was labored, and within an hour she was dead

At the post-mortem examination the abdominal cavity was found free from inflammation. The vermiform appendix had wound around the head of the cæcum and was lying posteriorly and to its right side pointing upward toward the liver. Its exact length could not be determined since its extremity was entirely destroyed by gangrene, but the portion remaining measured five inches. No cause of death could be found in lungs, liver, heart or kidneys. Though this case should more properly be classed with those in which the abscesses developed with a primary attack, it nevertheless exhibits in a most emphatic manner the enormous extent to which abscesses the result of appendicitis may burrow upward and downward before entering either the abdominal cavity or reaching the surface, and serves to emphasize the importance of earlier operation.

The third case is of B. M., æt. 34. He had always been strong and well until October 5, 1891, when he was seized with pain in the lower part of the abdomen. He was under the care of Dr. O. B. Campbell, who called me to see the case on October 10. Unfortunately my notes upon the case are not very full, but I found him somewhat tympanitic, with unmistakable evidences of an abscess over the cæcum. The next morning, with Dr. Campbell and Dr. Nevison I opened the abscess and removed the vermiform appendix without opening the abdominal cavity. The cavity was washed and packed with iodoform gauze. The subsequent history of the case was favorable and healing was rapid. On February 13, 1892, patient visited my office and said he was well. Immediately thereafter he resumed his daily work. About May 1, he came to my office and told me that after working about two weeks he began to feel badly; and developed a serious cough. At this time he was coughing frequently and expectorating considerable quantities of material closely resembling anchovy sauce. He was carefully examined by Dr. Edward F. Cushing, who reports as follows: "You will find in the left back dulness, with absence of fremitus and feeble breath sounds. Below the eighth rib is a narrow strip of bronchial breathing with increased voice sounds above; similar sounds in the lateral and anterior aspects of the chest; heart is not displaced but I expect an exploratory puncture would discover pus and that his purulent expectoration represents an empyema broken into the bronchial tube. The expectoration I have not examined, but it is chocolate color and strongly suggestive of hepatic origin, though I did not discover any especial enlargement of the left lobe of the liver." The expectorated pus closely resembled in color anchovy sauce, spoken of by Osler as indicative of liver origin. My own examination had previously led me to a similar conclusion as that of Dr. Cushing, and after observing the extent to which the case previously described had burrowed upward in the direction of the liver, together with other cases of a similar sort which I have seen, I have no question that the conclusion arrived at by Dr. Cushing is the correct one. Unfortunately, I have not had further opportunity of observing the case. Though the primary operation in this case was apparently completely successful, its further history renders it probable that an earlier operation might have wholly averted its serious secondary manifestations.

The fourth case was of F. H.. male, æt. 23 years. Previous to 1877 he enjoyed good health. That fall he had what was called inflammation of the bowels, accompanied by vomiting and pain, chiefly in the cæcal region. He seemingly recovered from this attack, but six weeks later had another. These attacks recurred at intervals of about six weeks, accompanied by vomiting and pain in the cæcal region and occasionally attended by chills. In 1881, four years after the primary attack, patient thinks he passed some pus, per rectum, but never noticed it at any other time. In 1883 the patient was kept quietly at home on one floor during six months, in hope of curing his malady by rest. Much of the time was spent in bed. In 1889, twelve years after the primary attack, the patient was laid up in bed for two weeks. For nearly six years he had suffered from repeated attacks of vomiting with pain in the right side of the abdomen, the attacks being accompanied by tenderness and often by a chill. Until I saw the patient in Sept., 1889, no diagnosis of the case had ever been made. Just inside of the anterior superior spinus process of the ileum I could find, on deep pressure, a small resisting mass; pressure produced pain. I gave him a cathartic. On the day following, I saw him in consultation with Dr. H. K. Cushing. A very small indurated mass could still be felt deep in the right iliac fossa in the region mentioned. An operation was agreed upon, and this was performed in Charity Hospital on Feb. 7, in the presence of the House Staff and Dr. N. Stone Scott. A curved incision was made to the inner side of the right anterior superior process of the ileum. The cæcum was pushed inward and the abdominal cavity was not opened. In the iliac fossa, wholly posterior to the cæcum was found a cavity containing pus. The cavity measured about one-half inch transversely, and extended from a little above the spine of the ileum downward to Poupart's ligament. This was cleared, washed and packed with iodoform gauze. The progress of the case was very satisfactory, and the patient has been entirely well since the operation and free from the attacks of pain, fever and chills, which previously had wholly incapacitated him for business, and although a small sinus has remained unclosed, the patient has been able to fill an important business position, and has enjoyed good health. The striking feature in this case is that a young man during twelve years should have passed through the hands of several physicians, having chills and attacks of vomiting and pain referred to the region of the cæcum, during this time being largely incapacitated for business, without his malady having been diagnosticated or an operation proposed for his relief.

The fifth case is O. L., male, æt. 19. He had good health and has a good family history. In December 1891 patient was seized with pain in the region of the cæcum, and was sick for 7 weeks, his temperature reaching 103. Most of the time patient was in bed. At the end of this time he was beginning to move about when he had a relapse and from that time until operation there were frequent attacks of pain in the region of the cæcum. The bowels were regular during this period. April 26, 1892, I first was asked to see the case, by Dr. Upson of Conneaut. The abdomen was flat, and to secure satisfactory examination, he was placed under an anæsthetic, since without it he resisted deep pressure. Dr. W. J. Scott examined the case with me. Upon deep pressure, a distinct resistance could be felt in the region of the cæcum, extending a short distance upward. Under an anæsthetic the right leg could not be fully extended, and when the patient walked, he inclined markedly to the right side. It was evident that the psoas and iliacus muscles did not permit perfect extension. May 12, I operated at Charity Hospital, in the presence of Dr. Upson of Conneaut, Dr. Bagot of the Rotunda Hospital, Dublin, Dr. Nevison, and the House Staff. An incision through the right linia semilunaris was made from the level of the anterior superior spinus process of the ileum upwards. The peritoneal cavity was opened by an incision 5 to 6 inches in length. The head of the colon was examined, but there was no vermiform appendix to be found free in the abdominal cavity. Slight induration, but no fluctuation could be felt behind the cæcum. The cæcum was drawn toward the median line and dissected from the iliac fossa, when the finger entered a small cavity perhaps ¾ of an inch in diameter, extending vertically for about 5 inches, its lower extremity being nearly down to Poupart's ligament. A very small amount of inspissated pus was found and in it was a small concretion from ½ to ¾ of an inch in diameter. The entire length of the sinus could not accurately be determined since at either extremity its calibre was small. Remains of the appendix were not found since it would have increased the dangers of the operation to have persisted in searching for them. The patient's condition was very weak, and his pulse rapid before the operation, and though the operation seriously taxed his strength. his progress has been on the whole, very satisfactory, and he is now up and about, and seemingly on the road to recovery.

The sixth and last case is one of extreme interest, and one in which I have only been lead to a diagnosis after operating upon a number of similar cases. The patient, F. H., was about 35 years of age. He had always enjoyed good health. On November 26, 1889, patient was feeling very well. His physician, Dr. Sabin, of Warren, gave him a cathartic and the next day patient felt better, and the night of the second day, attended a lodge meeting where he was seized with intense abdominal pain. He reached home with great difficulty, and soon afterwards vomited. He was most comfortable lying in bed with his legs flexed. The pain was general over the abdomen; hot application gave no relief, but Dr. Sabin secured relief after one to two hours by the application of chloroform. Patient's bowels moved with saline, and the highest temperature was about 101½. A week after the attack, patient walked to his office. The patient was up and about until December 15. and on December 16, Dr. Sabin could find some tenderness in the region of the cæcum, though there was no tumor. Temperature that evening was 102, and the highest temperature reached before I saw the patient was 103. December 31, about five weeks after his first attack I saw the patient with Dr. Sabin. He bore the appearance of one long sick, and was thin and sallow, and was having severe night sweats. Though when well patient had slept upon his face, he now sleeps best upon his right side. When he turns to the left side, he must prop up his abdomen with a pillow, otherwise he feels a dragging sensation in the right side. When lying upon his back he can straighten his legs without pain, His bowels have moved regularly; he has had no chill, but early in the evening has wanted to be warmly covered. On examination there was no unnatural fulness anywhere. In the region of the cæcum there was no induration but there was some tenderness on deep pressure. The diagnosis of appendicitis was made and an operation was advised, and for this purpose the patient was brought to Charity Hospital in Cleveland, on January 3. At this time he was seen in consultation by Dr. H. K. Cushing, Dr. Sabin and myself. Since I had seen him in Warren, the tenderness in the right iliac region had wholly disappeared. The patient also said he had some pain at the base of the lungs, and some dulness could be discovered at this point. The change in symptoms led us to defer the operation, and on January 7 the patient was seen in consultation by Drs. H. K. Cushing, W. J. Scott and myself. The conditions remained the same as on the week previous, and the diagnosis of appendicitis was thrown so much into doubt by the disappearance of pain in the region of the cæcum and the appearance of dulness at the base of the right chest that operation was still deferred. The evening temperature had ranged from 103 to 104. As time progressed there was a gradual increase of dulness in the right side corresponding to the right lower lobe of the lung, accompanied by slight broncophony, a few moist râles and cough with some purulent expectoration. In Febuary, the patient's condition gradually improved, the region of the cæcum remained free from pain and the temperature did not exceed 102 and it seemed not improbable that it was an obscure case of tuberculosis. This opinion gained strength since there had been cases of tuberculosis in the family. On February 14 I saw the patient at his home in Warren. The condition of the lung seemed slightly improved, but the patient was much the same. On March 16, I again visited the patient in Warren. The dulness in the chest had increased slightly, and there was an absence of respiration at the base. For the purpose of exploration an aspirating needle was inserted; though inserted but a short distance and in the usual manner, there immediately followed a most copious discharge of blood from the mouth, which came near suffocating the patient. He recovered from this however, and seemingly improved. The winter of 1890 and 1891 the patient spent in the South, troubled with a cough and expectoration, and it seemed probable that the case was one of tuberculosis. He gradually improved, however, and was able to do some professional work, which was that of a lawyer. Later however, he developed trouble in the right leg and on October 1, I opened an extensive abscess of the right leg. These abscesses formed repeatedly, extending from the knee almost to the groin, and have been repeatedly opened by Dr. Sabin. In January of the present winter patient's condition was so low that it was supposed that he could live but a few days; he has however improved considerably. From a further study of the subject of appendicitis and experience gained in operating upon these cases, I am convinced that this case was primarily one of appendicitis. Though the local manifestations were followed by extension of the abscess upward either by absorption or directly to the right thoracic cavity, subsequently the progress of the disease has been downward, and the right thigh has been involved in repeated and extended suppuration. The grave error in the case was that it was not operated when first seen, as a case of appendicitis. I do not believe that tuberculosis ever played any part in the case.

It is unnecessary for the purpose of this paper to multiply further cases. Though I might cite others pointing to the same conclusion, those cited are sufficient in number to demonstrate the fact that cases accompanied by pain in the region of the cæcum with tenderness and perhaps vomiting, though there is no apparent temperature or collection of pus are of extreme gravity, and as positively demand operations as those in which collections of pus are evident.

The question remains, how are such cases to be operated. I have tried both the extra-peritoneal and the trans-peritoneal method. Though it is of course desirable to avoid the opening of the abdominal cavity when possible, and though I have repeatedly succeeded by this method in relieving a deep seated appendicitis, there are many cases in which operations must fail unless the abdomen be opened, for without it, the whole region of the cæcum cannot be thoroughly examined, and the danger of tearing the tissues about the cæcum, for the purpose of locating an appendicitis, accompanied by very slight collection of pus, is greater than freely to open the abdominal cavity, find the cæcum, locate the seat of the appendix and open the inflammatory mass which may contain only a small amount of pus with perhaps a gangrenous vermiform appendicitis, and a foreign body. During the operation the abdominal cavity may be shut off by means of tampons of iodoform gauze, and when the inflamed mass is opened, by means of a stream of water from a fountain syringe, all inflammatory material may thoroughly be washed away, and the abdomen kept free from contamination. A good way of dressing the wound is to carry a large drainage tube down to the point of inflammation and then thoroughly to pack the opening about it with iodoform gauze, By these means, the abdomen is kept closed from infection, the free discharge of pus through the tube is insured, and the iodoform gauze packed about the tube will upon its removal, leave a passage for the discharge of material from the inflamed cavity.

As to whether such operations should be performed in the intervals between attacks or only when an attack is in progress cannot be answered by any general statement. Each case must be decided upon individually. There are many cases however where there are chronic inflammatory conditions, such as several which have been cited in which operative interference offers the only opportunity for cure which can rationally be expected and in such cases I am strongly of the opinion that the seat of disease should be sought out without awaiting the occurrance of an acute attack. Since such operations are a severe tax upon the patient his opportunity for recovery may be enhanced by an operation performed in his interval between attacks, when his general condition and strength are better.

REPORT OF A CASE OF GUNSHOT WOUND OF LIVER AND STOMACH. LAPAROTOMY. RECOVERY.

Read in the Section of Surgery and Anatomy, at the Forty-third Annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY JAMES T. JELKS, M.D.,

OF HOT SPRINGS, ARK.

Formerly a Member of the State Medical Society of Georgia; a Member of the Southern Surgical and Gynecological Society, Mississippi Valley Medical Society, Chicago Medical Society, Hot Springs Medical Society, State Medical Society of Arkansas, American Medical Association; formerly Secretary of the Obstetric and Gynecological Section, American Medical Association; and late Professor of Surgical Diseases of the Genito-urinary Organs and Venereal Diseases in College of Physicians and Surgeons, Chicago, Ill.

Some time in April I received a note from Dr. Eugene Hay, saying he had a case he thought required a laparotomy, and asking me to come to him.

I responded, and found the doctor at what is known as "Dirty Six," a tough suburban resort. In a small cottage, lying on a bed, was a young man apparently 22 years old. He was resting very quietly, his face covered with sweat. Turning him partly on his right side, Dr. Hay showed me the wound of entrance—a bullet hole 3 inches to the left of spinal column and just at lower border of last rib. There was no wound of exit. He had vomited quite a quantity of blood. There was no tenderness; pulse 70 but quite soft, and as stated above, his skin was covered with sweat. I agreed with Dr. Hay that indications pointed to a laparotomy, and so advised the friends of the young man and the man himself. At first he refused an operation. Then stating the case to him as clearly as I could, telling him what the hæmorrhage meant, and what his prospects were both without and with the operation, he consented to have it done. This was about 3 A.M. We then proceeded to get ready as best we could. There was nothing in the house; we had to borrow the table, lamps, and even the hot water, from a restaurant across the street. So after boiling my instruments, I got everything in the best shape I could, and again asked him if he wanted the operation; he again consented, and was brought to the table. Dr. Hay gave the chloroform until the patient was anæsthetized, when it was turned over to Dr. How, and Dr. Hay assisted me.

The abdomen was then rendered as aseptic as we could make it with green soap, bichloride and ether, and by the light of the lamps I made an incision from the ensiform cartilage to the umbilicus, afterwards prolonging it about 2 inches below the latter point. All hæmorrhage was checked before the peritoneum was opened. When we entered the cavity of the abdomen some blood was visible, but not a great deal. At this time patient began to vomit blood, and during the straining the stomach was pushed out of the abdomen and lay in my hands; as it did so the bullet also appeared to the left of the median line, and lying loose. This was removed and handed to a bystander. I then carefully examined the anterior and posterior surfaces and the greater curvature, but could find no wound in the stomach. I then passed my fingers along the lesser curvature, but still could find no wound. Continuing my search, I found a bullet hole in the posterior edge of the liver, to the right of the aorta. By this time the flat sponges which I had used to keep the intestines in the cavity were with the latter extruded, and lay on the patient's abdomen. The intestines were carefully wrapped in warm towels and kept warm with boiled water, while I continued to search for other wounds. Finding none in the intestines, and being unable to stitch the hole in the liver, I wrapped a glass drainage tube in iodoform gauze and passed it down underneath the stomach, and placed it in the wound in the liver. This bag of iodoform gauze I packed with more gauze, thus ballooning it, and a strip of same material was passed down the tube into the hole in the liver. After this was done, I flushed the cavity of the abdomen with warm sterilized water by passing the nozzle of the irrigator down into the bottom of the pelvis and allowing the water to fill and overflow the abdomen. In doing so some clots and blood were washed out. I then proceeded to sponge out the cavity, getting it as dry as I could. During all this time Dr. Hay was assisting me, while Dr. How was giving the anæsthetic. When this was completed, we had great difficulty in getting the intestines back into the abdomen. Patient's pulse began to grow quite weak, and hypodermics of whisky and digitalis were given. Finally the abdomen was closed with sutures of braided silk, and coaptation sutures of plain silk, the drainage tube coming out at the upper end of the incision; the iodoform bag with its packing shutting off the abdominal cavity from the wound in the liver, and also from the posterior surface of the stomach.

I saw the patient a few times afterwards with Dr. Hay, and for the subsequent data I am indebted to him.

The glass drainage tube was removed on the third day, and on the fifth the iodoform gauze was taken out perfectly sweet; drainage of bloody serum had been perfect. Into the place of the large bag of gauze I now pushed, with the sterilized handle of a tenaculum, a strip of same material, and allowed it to remain several days. This latter was removed by Dr. Hay and the hole closed with a suture.

Day after the operation temperature was 99° in the morning and 100° at night. During the next day he had considerable pain in the abdomen, with tympanitis. We now gave him saline purges until his bowels moved some eight or ten times, with entire relief of the tympany.

During the next five days he was nourished by the rectum. He was allowed nothing by the stomach but crushed ice for three days, save the saline mentioned, when a little water was permitted. His temperature ran from 99° to 100° during the forenoon, and to 100° or 101° during the afternoon. On tenth day we removed the sutures and found perfect union, with one stitch hole abscess. Dr. Hay redressed the wound. The day after he telephoned me that the man had been coughing and had torn open the line of union. He visited him and found the line open for about 4 inches, with a knuckle of intestine protruding. This he replaced. There were adhesions between the parietal and intestinal peritoneum throughout the remainder of the open wound. These he separated with his fingers and put in several sutures through all the tissues, and brought the wound together. The patient stood this without an anæsthetic. These stitches were allowed to remain in place for two weeks, when they pere removed, the line of union being found strong. The wound was now covered with aristol and carbolized gauze, and several adhesive plasters strapped the latter in place, thus supporting the parts to prevent a new rupture.

During the healing process patient complained of a constant pain in one spot in the line of incision, which I think may be explained by the adhesions which had been formed. At the end of three weeks the young man was well, and in four weeks was up. He now has no trouble save some "bloating" of the abdomen from gas.

Discussion.

Dr. Christian Fenger, of Chicago, in opening the discussion, said the main feature in wounds of the liver is undoubtedly the hæmorrhage, and this is probably better stopped by packing the wound with iodoform gauze than in any other way. Ligatures will not, of course, hold in the liver substance. He had seen one instance of subcutaneous rupture of the liver, and in operating for a tumor of the abdominal cavity a year after the infliction of the injury, the wound in the organ was still visible.

Dr. E. H. Gregory, of St. Louis, wanted to know whether, in Dr. Jelk's case, hæmorrhage was going on at the time of operation. Being answered in the affirmative he said, that though he thought the operation was not wrong for it fulfilled what seemed to be the indications, he, as a conservative surgeon, would like to know whether the man might not have recovered by his line of treatment, viz., by leaving him alone. He believed that by following this course, we should have had another case of recovery without operation.

Dr. Thorn, of Toledo, reported a case in which there was a small laceration in the liver, and the patient died from loss of blood. He believed operation would have saved his life.

Dr. D. A. Watson, of Jersey City, had seen a great many cases in his experiments on animals, and in a vast majority, even though the laceration was very extensive and the wound filled with blood, the animal recovered, except were the main arteries were involved. He thought danger lay in the fact that the bullet might carry septic material into the abdominal cavity, but beyond this he believed we are more afraid of lacerations of the liver than we have any just right to be.

Dr. Murdoch, of Pennsylvania, defended the operation on the ground that a surgeon would feel that he had not done his full duty if he did not open the abdominal cavity and notwithstanding what might be said about the innocency of a bullet in the cavity, he thought any man would rather have it out.

Dr. Gregory did not wish it to be understood that he objected to the operation, in fact, he might have been betrayed into doing it himself, though he felt sure he would regret it later. He thought that the bullet left in the cavity would have done less harm than the operation.

Dr. Griffin, of Missouri, reported three cases of gunshot wounds of the abdomen which he had seen within the last year and in all of which he had operated.

Dr. Walker, of Tennessee, reported a case in which the patient refused operation. The autopsy showed anterior border of liver torn to shreds. Patient died of hæmorrhage.

Dr. McIntyre, of Missouri, said there was no shadow of doubt that men did get well who had these injuries, but he congratulated Dr. Jelks on the success of his operation and thought that a ball rolling about in the cavity of the abdomen would not be likely to become encysted.

Dr. Dolan, of St. Louis, thought no surgeon would refuse to operate where there was vomiting of blood as in Dr. Jelk's case. He could not see how this symptom could occur if the stomach were not punctured.

Dr. Palmer, of Wisconsin, considered the case to be one of those cases in which it is the absolute duty of the surgeon to operate.

Dr. Quinby, of Jersey City, said it was his rule to operate when there was a foreign body where it might do harm.

Dr. Jelks felt sure that if Dr. Gregory had been called to the case he would have diagnosed gunshot wound of the stomach. The surgeon's duty is to offer the operation and if accepted he must do it. If we wait twenty-four hours before operating we have passed the golden opportunity. Statistics show 63% of deaths in liver wounds. Experiments have demonstrated that the blaze of fire renders a bullet aseptic. The harm is done in its passage, not after it has stopped.

SOCIETY PROCEEDINGS.

American Otological Society.

Twenty-fifth Annual Meeting, held at the Fort Griswold House, New London, Conn., July 19, 1892.

(*Continued from page 142.*)

It seems unaccountable that only one of these cases resulted fatally when it is known that any considerable quantity of dead bone in the vicinity of the brain, may induce fatal cerebral disease. The author did not think it proper to attempt the removal of dead bone where the meninges are in danger of being encroached upon.

Numerous cases are on record (one in the author's book) where a considerable portion of the bone has separated leaving an uncovered meninges without fatal consequences. Moreover when all dead bone is removed, reparative action does not commence until a new barrier of dead bone has been established.

B. Alexander Randall, M.D., of Philadelphia, read a paper entitled

PRELIMINARY NOTES ON CRANIOMETRIC STUDIES IN RELATION TO AURAL ANATOMY.

The author referred to the numerous careful studies made of the temporal bone with special relation to operative procedure and the conflicting results of Koemer and Schultzke as to a relation between the cranial index and the dangerous position of the lateral sinus and the middle cerebral fossa. Recognizing from the first the need of more extensive examinations, he had been accumulating data bearing on the matter, and offered now a preliminary report principally to secure criticism of his methods. Only 122 skulls, 73 broad headed, 33 long headed and 16 medium in index were used in the tabulation, and the only clear showing was that maximum or minimum dimensions might be found on either side and in any form of skull. The greater danger of the right side and of the brachycephalic skull receive slight confirmation, the cerebral fossa being actually more often lower on the left, but no deductions should be attempted from so small a series of studies, and any indications are probably worthless which are derived from less than one thousand skull measurements.

Dr. Charles J. Kipp, of Newark, New Jersey, reported a case of purulent inflammation of the middle ear with double optic neuritis and other symptoms of intra-cranial lesion, but without tenderness of the mastoid process, in which the opening of the mastoid cells was followed by rapid subsidence of the optic neuritis and cure of the disease.

Particular attention was called to the absence of tenderness over mastoid even on percussion, and to the desirability of repeated ophthalmoscopic examination in prolonged middle ear disease.

Dr. C. J. Blake, of Boston, read a paper entitled

MASTOID CASES.

Of 25 cases of mastoid congestion and inflammation seen in the first six months of this year, 3 were treated by continuous gold coil, with excellent effect. The remaining 22 cases came to operation at various stages of the mastoid disease and with various complications. Two cases died, one on the 9th day, complication with pneumonia, and the other on the 10th day with meningitis from extension of the suppurative process from the middle ear through the tegmen lympani.

Dr. H. Knapp, of New York, read a paper entitled

CASE OF CHRONIC PURULENT OTITIS MEDIA, OLD PULMONARY TUBERCULOSIS, OPENING OF MASTOID, DEATH FROM ACUTE BASILAR MENINGITIS. AUTOPSY.

The patient was a healthy looking man, age 35 years. About the middle of April 1892, he began to complain of headache apparently due to neuralgia. This however, was succeeded by slight elevation of temperature, but no change in the pulse, no tenderness over the mastoid, pupils normal. By April 27, there was drowsiness with nervous movements of the hands. Meningitis dependent upon aural disease was diagnosed by the attending physician. The patient was seen by two prominent neurologists who diagnosed cranial abscess from ear disease. The speaker saw the case May 3. There had been discharge from the right ear for three years, which had ceased during the previous week; temperature 102.2. Headache, stupor, incoherent difficult speech, delirium, pupils and fundus normal, no painful spot on percussion of skull. The diagnosis was concurred in and operation urged, which was done next day. The mastoid was found sclerosed throughout. The superficial portion of the bone presented some evidences of disease, but the deeper the bone was exposed, the healthier it appeared. The operation was then suspended. The patient continued to sink and died a few days later.

The autopsy showed marked evidences of basilar meningitis. The lungs were then examined and distinct evidences of pulmonary tuberculosis found. The patient had presented no symptoms suggesting examination of the lungs and all the indications pointed to cranial suppuration following aural disease.

Dr. J. B. Emerson, of New York, read a paper entitled

A CASE OF PYÆMIA FOLLOWING ACUTE SUPPURATIVE OTITIS. RECOVERY.

A. D., female, 24 years of age, admitted to Manhattan Eye and Ear Hospital, April 4. April first, pain appeared in the left ear, followed on the third by discharge. The ear trouble had followed grip. Temperature on admission was 100° pulse 104, free purulent discharge. No special tenderness over mastoid, no redness or œdema. The temperature to April 10, varied between 101° and 102°; April 10, morning temperature 101°, slight chill: evening temperature 105°, pulse 125. No pain except in back of neck. Tenderness much less over mastoid and left side of head, no redness or œdema over mastoid; ear discharging profusely. Condition continued about same until April 15, when evening temperature reached 105.4°, no redness, œdema or tenderness over mastoid, free discharge from ear, signs of septic pneumonia. The general condition of the patient continued to improve, but an abscess developed over the right sterno-clavicular articulation. Later a second collection of pus formed over the sternum. May 18, an abscess formed above the sternum. This was opened. May 29, swelling formed over left side of the neck. June 3 an incision was made into the swelling and pus found at a depth of one and a half inches; no direct communication with the mastoid could be found. Following this the patient slowly and steadily improved and was discharged August 4, the treatment extending over a period of four months.

Dr. T. Y. Sutphen, of Newark, N. J., read a paper entitled

MASTOID OPERATION IN A CASE OF MIDDLE EAR DISEASE WITH SEPTICÆMIC SYMPTOMS AND CEREBRAL COMPLICATIONS.

March 17, 1892, the speaker was called to see Miss B. K., æt. 16 years. There had been chronic otitis media of left ear for several years. For a few days there had been intense pain and a temperature of 105°. No sign of mastoid trouble other than the pain. The next day there were general septicæmic symptoms with chills, alterations in temperature and vomiting. A hard swelling beneath the sterno-cleido-mastoid muscle was discovered. May 22, the mastoid was opened; there was only a drop or two of purulent fluid. The condition of the patient continued very unfavorable until May 30, when pus began to flow freely from the mastoid wound, the temperature then fell to 99° and the patient made a rapid recovery.

Dr. Gorham Bacon, of New York, read a paper entitled

A CASE OF MASTOID DISEASE FOLLOWING AN OPERATION FOR THE REMOVAL OF ADENOID VEGETATIONS.

The patient, Annie R., æt. 30, came to the New York Eye and Ear Infirmary, Feb. 16, 1892. She gave the following history: She said that a physician had on Feb. 8, removed adenoid vegetation from the naso-pharynx, by means of the index finger and completed the operation the following day with forceps. She had a subacute pharyngitis at the time. Two days after the operation, she had severe pain in the right ear followed by a muco-purulent discharge on Feb. 16.

On the day of admission, she had a very anxious appearance, and had suffered from well marked mastoid symptoms for several days. She was immediately put to bed, and the Leiter coil applied, and the ear douched frequently with a warm boracic acid solution. Under the treatment the mastoid symptoms soon disappeared.

Feb. 23, a periosteal abscess on the right side was opened and about a drachm of pus escaped. An incision in a similar abscess on the left side gave a negative result. The patient made a good recovery and at no time did the temperature go above 100° F. The case was reported because the writer had not seen in the literature of the subject, any mention made of acute otitis media and mastoid disease following the operation for removal of adenoid vegetations. It is possible, however, that the carbolic acid solution which the patient was advised to syringe through the anterior nares by the physician before she came under the author's care might have had something to do with the etiology of the disease.

Dr. Samuel Theobald, of Baltimore, read a paper entitled

THE VALUE OF WEAK SOLUTIONS OF BICHLORIDE OF MERCURY IN THE TREATMENT OF OTITIS MEDIA SUPPURATION.

The author stated that boracic acid in fifteen grain solution was still, as it had been for some years, his first choice in the treatment of all cases of recent and in most cases of chronic otorrhœa. Boracic acid, however, occasionally fails to accomplish what is expected of it, and in exceptional instances aggravates rather than lessens the inflammation. It is in these cases that the speaker has recently used with very good effect, weak solutions (usually 1 to 8000) of mercury bi-chloride. The ear is simply syringed with the solution. Unlike some who have recommended the use of this agent in otorrhœa, he has not usually found it necessary to repeat the syringing more than once in twenty-four hours. Notes of several cases were given in which a prompt arrest of suppuration and disease of the perforation in the tympanal membrane followed the employment of the bi-chloride solution after boracic acid had been used without effect.

Dr. H. Knapp, of New York, exhibited a specimen showing perforation on the medial side of the mastoid, removed from a patient dying from cranial abscess.

Afternoon Session.

Dr. D. B. St. John Roosa, of New York, read a paper entitled

WOUND OF THE LATERAL SINUS IN THE COURSE OF MASTOID OPERATION FOLLOWED BY SEPTICÆMIA WITH RECOVERY.

The speaker remarked that there had been a number of cases reported in which the sinus had been wounded during operation, but that so far as he was aware, death had in no instance resulted from this accident.

The patient, a young lady, æt. 23 years, had for years suffered from recurrent attacks of suppuration of the left ear. It was thought that the mastoid was probably in a carious condition, and it was decided to open it, the drill being used. As soon as the bone was perforated the drill dropped into a large cavity, and the removal of the instrument was followed by a gush of venous blood which could not be checked by ordinary means. It was believed that the lateral sinus had been perforated. The wound was plugged with iodoform gauze. Four days later, when the wound was dressed, there was no trouble from bleeding. Symptoms of septicæmia then set in, but after two months of expectant treatment the woman made a complete recovery.

Dr. F. L. Jack, of Boston. read a paper entitled

REMARKABLE IMPROVEMENT IN HEARING BY REMOVAL OF THE STAPES.

In June, 1892, the author operated on a case of chronic suppurative otitis in a girl of 12 years. After removing portions of the membrana tympani, malleus and incus, examination showed the head of the stapes to be carious and it was decided to remove the bone. Previous to operation there was very little hearing in the affected ear. On the morning following operation the hearing was much better, and this fact suggested the possibility of good results from the removal of the stapes. Previous to this the speaker had operated on two cases of chronic non-suppurative middle ear inflammation by removal of the drum membrane, malleus and incus. The results as regards hearing were not satisfactory. Removal of the stapes is much better in its results and in the author's experience, there had been no operation was completed without misadventure and for a time the patient was in a promising condition. But his bronchitis increased and his heart weakened, and he died. The writer of the account states that this operation has been recorded not more than three times in all countries.

NECROLOGY.

Dr. Frazer C. Fuller, of New York City, lost his life in consequence of a fall from his horse, while at the State Camp at Peekskill. He was a member of a troop of militia and on summer camp-duty at the time of his injury, which was a fracture of the leg. A short time after his removal to his home pneumonia set in, followed by pleurisy and septicæmia. He was born in Boston in 1860. He was graduated from the Columbia College Medical Department about ten years ago. He was an interne at Bellevue Hospital for a year, and not long after was appointed to the visiting staff at Charity Hospital. He was prominent in the scientific work of the Neurological and Pathological Societies, and a frequent contributor to the medical journals. His accidental death was a most unexpected and mournful event to a large circle of acquaintances and patients.

Dr. Luther P. Kennedy, of Atlanta, Georgia, died early in June, at his former home at Due East, South Carolina. He was one of the editorial staff of the *Atlanta Medical and Surgical Journal*, and an assistant to the chair of obstetrics and gynecology at the Atlanta Medical College. He was graduated from Erskine College and a post-graduate student for one year at the Johns Hopkins University. His medical degree, obtained in 1887, was that of the New York University Medical Department. He spent a year or more in the hospitals on Blackwell's Island and elsewhere near New York City. The indications were unmistakeable that Dr. Kennedy would not only reach a high place in his profession, but also become a most effective medical teacher. He was a close observer and student and was able to impart his knowledge to others in a terse and forcible diction. His final illness was the result of an exhaustive attack of typhoid fever.

BOOK REVIEWS.

The Modern Materia Medica, for Pharmacists, Medical Men and Students. By Henry Helbing, F. C. S., London, Eng. Third edition. Lehn and Fink. 1892. New York. 8vo. 212 pages.

The claims of the publishers regarding this little handbook are that it contains the latest corrections and additions regarding the new remedies that come to us from Germany, chiefly. The new drugs, asaprol and diaphtherin—now about a month old—are among the articles described in this third edition. The older ones, concerning which new points of development have been brought to light, have been written up to date and the matured opinions of many observers introduced. Some of the more lengthy descriptions have been rewritten throughout in the light of recent clinical reports. The amount of patience on the part of the editor in his researches is evidenced by the fact that the index contains six hundred references to the chief new remedies and their synonyms. On this account the book makes itself especially attractive to the busy practitioner, and also to [illegible] professor or teacher whose memory is fickle on the points of coal-tar product chemistry.

Part II of this book, called an Appendix, contains notes of the non-synthetic remedies, and some others, that seem to require a less detailed description. There are tables of considerable value in the afterpart of the book, as Demme's dosage of antipyretics for children; solubility of the synthetic new remedies; melting and boiling points of those substances in centigrade degrees. The author adverts to the very persistent, though almost unavailing, search after a synthetic substitute for quinine, as the probable occasion of a vast number of serviceable medicaments, external as well as internal. He says "Since the time when the modern chemist first became fired with the ambition to win fame and fortune, at one stroke, by the synthesis of quinine, the number of remedies turned out yearly from the chemical laboratory has gone on speedily increasing, and if the original aim of the work is still unaccomplished—as the process of Grimmaux and Arnaud is but a partial solution of the problem—yet among the very considerable number of compounds produced, some have been found capable of replacing the natural alkaloid in many cases, while in others they seem to be even superior to it in therapeutical activity, reliability or safety."

The publications on materia medica, averaging as they do a book a month, are the most active present competition in the field of medical literature. Their volume is something unprecedented and well-nigh bewildering. This small treatise, on the contrary, has the advantage of clearness, compactness and singleness of purpose.

Transactions of the American Surgical Association, Vol. ix. Edited by J. Ewing Mears, M.D. Philadelphia: Printed for the Association by Wm. J. Dorman, 1891. Cl. 8vo, pp. 508.

Most of the addresses and papers in this volume have been printed in the current medical journals, and are already common property, but we have them here collected in one volume, thus constituting a series of surgical essays of the highest class, by surgeons of National reputation.

President Mastin, in concluding his excellent address, recommends the project of establishing a monument to the late Professor Samuel D. Gross. A statue at Washington is the form commended.

The necrology report includes biographical sketches of Dr. Truman H. Squire, Prof. v. Volkmann, Prof. v. Nussbaum, Dr. Richard J. Levis, Dr. David Prince, Prof. Chas. T. Parkes, Dr. T. B. Reed and Prof. H. J. Bigelow.

The volume should be found in the library of every progressive surgeon.

Prevention of Blindness in Rhode Island.—The following enactment was passed April 19, 1892, by the General Assembly of Rhode Island, its intent being to diminish the amount of ophthalmia neonatorum, and its sequels, which has its origin in grossly ignorant midwifery.

Section 1. Should any midwife, or nurse, or person acting as nurse, having charge of an infant in this State, notice that one or both eyes of such infant are inflamed or reddened at any time within two weeks after its birth, it shall be the duty of such midwife or nurse, or person acting as nurse, so having charge of such infant to report the fact in writing within six hours to the health officer or some qualified practitioner of medicine of the city or town in which the parents of the infant reside.

Sec. 2. Every health officer shall furnish a copy of this act to each person who is known to him to act as midwife or nurse in the city or town for which such health officer is appointed, and the secretary of State shall cause a sufficient number of copies of this act to be printed and supply the same to such health officers on application.

Sec. 3. Every person who shall fail to comply with the provisions of this act shall be fined not exceeding one hundred dollars or imprisoned not exceeding six months, or both.

Sec. 3. This act shall take effect July 1st, 1892.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, AUGUST 6, 1892.

THE PRESENT STATUS OF THE TREATMENT OF POTT'S DISEASE.

The routine treatment of Pott's disease by this or that mechanical device can hardly be said to any longer obtain among orthopedic surgeons.

In choosing the plan of treatment for any given period it is customary to take into consideration the location of the disease, its tendency to destruction or progress towards repair, the severity of the symptoms, the complications, the age of the patient, the care which he may be able to command, and many other factors, such as materials at hand and the surgeon's skill and experience in working them.

The plaster jacket, applied during partial suspension, is still more widely used than either of the other means of immobilization. The materials are at hand or readily obtainable, so there need be no delay in its application, and the responsibility of its construction and perfect fit fall on the surgeon himself. On the other hand, it gives less perfect immobilization than a well fitting leverage brace, and if used without recumbency during the period of progression of the destructive process, cannot be relied upon to check the increase of deformity. Other corsets and jackets of plastic material are more difficult of construction and less effective in immobilization.

The antero-posterior leverage brace of soft steel grasps the pelvis above the greater trochanters, and the arms and upper chest above, and exerts as strong a leverage action as the soft parts will tolerate directly over the transverse processes of the vertebræ involved in the disease. When properly applied, it is probably the most efficient means of immobilization.

The cuirass (shellback) of steel and leather, gains something in effectiveness by extending its leverage to grasp the upper part of the thighs, but loses somewhat more in immobilization by distributing its leverage over the ribs, which are movable, instead of concentrating it upon the immovable transverse processes of the vertebræ. Each of the three plans aims to immobilize the area of disease by limiting the movements of the whole trunk, each supports more or less perfectly the superincumbent weight by leverage action, and diminishes the traumatism of the jars of locomotion. Used as ambulatory apparatus, neither fulfils all the indications for treatment in all cases.

It is no longer believed that traction made by suspension can be maintained by the plaster jacket or any other ambulatory apparatus, and all braces with crutch arrangements arising from a pelvic girdle have long since passed out of use. Traction, however, is still used to relieve pain and reduce deformity while patients are kept in recumbency in both stationary and portable beds, and thus used is a valuable agent.

The principles of treatment may be summed up as follows: Immobilize the area of disease continuously from the commencement of the treatment until a cure is effected; remove the superincumbent weight and avoid the traumatism of jars by keeping the patient recumbent until destruction has ceased and repair commenced; give good food, pure air and sunshine in abundance.

At another time we will discuss the treatment of the complications, namely: the deformity, abscesses and paraplegia.

GOLD CURE SPECIFIC.

The notoriety of this empiricism is rather a sad reflection on the general intelligence of the public, and also of many so-called physicians.

Charlatanism managed with psychological skill, assuming some discovery in science, that is a rational possibility, and covering up the real motives, is always attractive to the credulous and non-experts. But when it boldly proclaims theories outside the range of science and common sense, to be accepted entirely on faith, and the whole supported on a great pecuniary scheme to enrich the authors, it is difficult to understand how it should receive any serious attention. Compared with other empiric schemes, the bichloride of gold is very inferior in methods of management and assumed reality. It is the same old quackery, bold, ignorant and dogmatic, without a single original feature. The wild hysterical claims of cure by those who have used the secret remedy, is the same old story that is heard after every church and temperance revival. This posing as cured men by this or that means, with certificates from clergymen and others is common history in every community. It is a curious fact that mystery and concealment should add to its popularity, and still more unexplainable that both pulpit and press should be caught by such means. It is not strange that inebriates who have received benefit from the treatment should become enthusiastic as defenders of its merits, particularly when it is a pecuniary object to do so. The rapid growth of branch institutes for the treatment is purely commercial, and are managed in nearly all cases by so-called cured men. Precisely what the secret remedy is used under the skin, and other means, are of no interest except psychologically, and as phases of the evolution of the drink evil.

The success of the author financially in this country has developed the same boldness to conquer "other worlds." But, unfortunately, he assumed that entrance into societies and scientific support was a merchantable thing, to be bought. Also that the medical, as well as the secular press, was governed by public opinion, and ready to sell out when the price was offered. This was the "Waterloo for Keeleyism" abroad. The *British Medical Journal*, the *London Lancet*, the *Medical Press*, and several of our large dailies have denounced the whole scheme as the boldest quackery that has appeared for a long time. In the meantime, a house has been opened in London for the cure of inebriates, and the secret remedy offered for sale. An analysis of the remedy has been made, and found to contain no gold, but 27½ per cent. of absolute alcohol; and this statement is not denied by the managers of the cure. The Berlin authorities refused to permit a branch institute to be opened in Prussia, unless the remedy was first submitted to the public chemist for analysis. In all this the gold cure managers have displayed stupidity rarely seen among the common quacks. No attempts have been made to cover up the real pecuniary objects of enlisting capital and organizing companies for the sale of rights and remedies, as a matter of great profit. This combination of charity, business and science is new to our English relatives, and of course rejected. There is one feature of this gold cure specific worthy of study, that is the hurry and dash of the movement. Doing its work in three or four weeks, sending out the patient inflated with an idea of permanent cure, filled with extravagant expectancies and hope, and receiving full pay for this operation. This shows rare skill and full recognition of the brevity of this movement. The bichloride of gold will soon be among the things of the past; and also be a source of wonderment how it could grow and attract attention in this materialistic age.

THE SURGEONS AT HOMESTEAD.

In the report of the punishment of PRIVATE IAMS, at Homestead, as it appeared in *the daily press*, it seems that the colonel ordered him triced up by the thumbs, and the surgeons to stand by and see that no harm befell him.

In executing this order the surgeons took turns at standing on a chair, and counting the pulse of the man, and when it reached 120 ordered him to be cut down.

It is not the province of this JOURNAL to discuss the action of the colonel in ordering the punishment which he did. Whether he exceeded his powers or not, is the duty and privilege of others to determine. But the action of the surgeons becomes a fit subject for discussion by the medical profession. It is generally admitted that medicine is the healing art, and that the great duty of the physician is to relieve pain, and not to inflict it, except it be for the purpose of saving life or cutting short other suffering.

Nowhere can it be claimed that it is ever within the scope of their professional duties to be a party to brutality. Military medical officers are appointed as professional men, for the purpose of exercising their profession, and in the exercise of that profession they are not subject to the orders of the line officers. What medical man would carry out a line of treatment in a given case because ordered to do so by his superior officer in the line? If the colonel had ordered these medical men to cut off the leg of PRIVATE IAMS, no doubt they would have refused, because it would have encroached upon their medical functions. By what process of reasoning these surgeons determined that the colonel's orders had been complied with when the unfortunate man's pulse reached 120, it is hard to see. Why did they not order him down when his pulse reached 100? Or when it began to rise above normal? Or better yet, why did they not let the colonel himself decide when the punishment was complete, and then step in to extend relief so far as they could?

Suppose they had blundered, and let the man hang up so long as to end his life, who would have been guilty of the murder, they or the colonel? We care not what military law may be, it was the duty of these surgeons as medical men to refuse to carry out the orders of the colonel. to tender their resignations on the spot if necessary, or even to suffer punishment for insubordination.

In their action, if it be correctly reported, the profession has been outraged.

FARM COLONY FOR EPILEPTICS.

After a defeat in 1891, a salutary enactment was secured in 1892, in the New York legislature on behalf of the epileptic poor of that State. The text of the act is as follows:

SECTION 1. The Commissioners of the State Board of Charities are hereby directed to select a suitable site in the State of New York, on which to establish an institution on the colony plan for the medical treatment, care, education and employment of epileptics.

SECTION 2. The said Commissioners of the State Board of Charities shall have power to receive by gift or to contract for the purchase of such site for the location of buildings of said institution, subject however, to the approval of the next Legislature, to whom they shall report their action in the premises within ten days after the commencement of the session, together with plans and estimates for constructing buildings suitable for the purpose named in section one of this act; such site to include not less than three hundred acres, and such plans to provide for the accommdation of six hundred inmates and to admit such further extension of the buildings as may be necessary to meet future requirements of the State in providing for the epileptics.

Section 3. The said Commissioners shall be entitled to the payment of their traveling expenses while engaged in the performance of their duties under this act, and their account for such expenses shall be audited and paid out of the treasury, but they shall receive no compensation for their services. And the sum of one thousand five hundred dollars or so much thereof as may be necessary is hereby appropriated out of any moneys in the treasury not otherwise appropriated, payable on the warrant of the Comptroller, for the purposes of this act.

This act shall take effect immediately.

This is merely the entering wedge which it is expected will open the way for the establishment of at least one epileptic colony. A large sum of money will be needed yearly to carry the work forward from the point where this bill leaves it. At the present time there are considerable numbers of persons in the various county poorhouses, of all ages, suffering from varying grades of the disease, and almost entirely overlooked in the onward movement of charity as applied to the deficient class of citizens. As a rule, they have been without any proper care or treatment, and without training or employment, but the time approaches when every civilized State will be shamed into making an intelligent provision for this unfortunate, neglected class of patients.

EDITORIAL NOTES.

Dr. Chas. Warrington Earle, formerly connected with the College of Physicians and Surgeons, has been called to the chair of Obstetrics and Diseases of Children in Rush Medical College, recently made vacant by the death of the late Professor Knox. Dr. A. C. Cotton, who has for many years been connected with Rush Medical College as an Adjunct Professor has been elected Clinical Professor of Diseases of Children.

Pan-American Medical Congress.—On Thursday, July 15, Congress passed the Joint Resolution (Senate 76) as follows:

"*Resolved, etc.* That the President of the United States be and he is hereby authorized and requested to invite the several Governments of the Republics of Mexico, Central and South America, Haiti and Santo Domingo, and the Kingdom of Hawaii, to send official delegates to the meeting of the Pan-American Medical Congress to be held in the City of Washington, September 5, 6, 7 and 8, A. D. 1893."

University of Vermont Medical Department.—Important changes in the curriculum of the college at Burlington have been ordained. The length of the regular term has been ordered to be six months instead of four. It will begin in the last week in January. The preliminary course will not be resumed for the present; the lecturers who formerly participated in the preliminary term work will be given places in the regular corps, as vacancies arise. The special courses lately given to private classes will in large measure be made compulsory and become a part of the regular curriculum. Dr. W. B. Towles, of the University of Virginia, will continue to occupy the chair of anatomy, but the greater part of the practical instructions in this course will devolve on Dr. H. C. Tinkham, of Burlington. A class of forty-five students was graduated at the last Commencement.

Fatal Wounds from Fencers' Foils. Two Physicians Lose their Lives.—The *Lancet*, July 2, recently made mention of the death of an Italian physician in consequence of an accident received while fencing. Dr. Enrico Tanfani, of Florence, was considered one of the most promising of the young medical professors of that city. While at the Fencing School, pitted against a formidable antagonist, the foil of the latter had its button broken off, and a fatal lunge was made before the defect was noticed. His death was mourned by all classes, especially by the faculties of the military and medical training schools. With both of these he had been connected in a teaching capacity. His death took place June 14. About one month later, a very similar fatality befel an American physician, namely, Dr. Charles C. Terry, of Fall River. He was in the habit of taking weekly lessons in fencing, and his teacher was the instrumentality by which the fatal accident was produced. Dr. Terry was struck in the eye by a foil from which the button had unobservedly been broken. The weapon pierced the right eye and penetrated the brain. The victim fell unconscious at once, and he continued thus for about three hours and then died. The deceased was in his fifty-sixth year, a graduate of the Medical Department of Harvard, and for about thirty years a well-known practitioner of Fall River.

Chloralamide as a Remedy for Seasickness.—The *British Medical Journal* has recently contained some letters from men like Graily Hewitt, Robert Barnes and Professor Charteris, regarding their professional experience as to attacks of sea-sickness. The last named writer has a letter in the *Journal* for June 18, asking medical attention to a solution containing thirty grains of chloralamide, and a like amount of potassium bromide, in an ounce of menstruum; this has thus far been used with advantage, by persons who have had to make short voyages, like trips across the Channel or from Fleetwood to Belfast. This combination is dubbed by the author "chlorobrom." The passenger is recommended to take a podophyllin pill for one or two nights before the date of sailing, and when on board to remain for a time before rough water is reached, in a horizontal position with eyes shut, and to take no food on short trips. Dr. Charteris has received a letter from a medical man, who made the trip from Leith to Hamburg, wherein the correspondent states that the chlorobrom solution enabled him to stave off his old enemy—sea-sickness—by going to his berth early and getting a sound sleep, through the influence of the drugs, almost before the vessel got out into rough water. He was not sea-sick after he awoke, and was able to go to the table every meal, although the boat pitched greatly. On his next trip he avoided taking the medicine and he was very sick. A trip from Glasgow to Shetland was rendered unusually free from nausea and retching by means of small doses of the chlorobrom. The tossing of the steamer was violent enough to wake him up at night several times, but he experienced a few minutes of pleasurable reposeful feeling, which the rolling of the steamer seemed rather to enhance, and then he fell asleep again. A lady on the same trip, who had a like treatment, remarked spontaneously that during her intervals of wakefulness, "she enjoyed the rolling of the steamer." When the trip was at an end the patients were exceptionally free from exhaustion and weariness; some of them, in fact, reported themselves as "feeling quite vigorous and refreshed." The dose of chloralamide may be stated for an adult to be from a half-drachm upward, not exceeding one hundred grains in twenty-four hours. Professor Charteris closes his letter by saying that he has no hesitation in commending the drug to all who contemplate and who dread short and rough sea-voyages. Of longer transatlantic excursions he has not yet received details that will justify any sanguine expression. The reports thus far obtained warrant him in affirming that—

"1. This solution is absolutely safe and harmless, and that it produces a refreshing sleep without any baneful after-effects.

"2. When judiciously administered it prevents, and in all cases alleviates sea-sickness." The effects of the drug may be expected to begin in from thirty to ninety minutes after dosage; and the duration of sleep thus induced will be from five to eight hours. The quality of sleep is said to be refreshing, natural and devoid of disagreeable sequels in nearly all cases.

Nickel Carbon-Oxide.—Ludwig Mond reports a remarkable compound of nickel discovered by him. When that metal is exposed to the action of carbonous oxide gas at ordinary temperature the metal is acted on and converted into a volatile compound; very unstable and explosive. On exposing a heated body to it there is a deposition of pure nickel. When injected into the circulation of an animal, the bodily temperature is lowered in a marked manner. Other singular properties are said to be possessed by this newly discovered substance, which is already in the hands of physiologists for purposes of confirming former and of making new observations.

How to Choose a Medical Specialty.—Dr. William Osler delivered an address, in May last, before the American Pædiatric Society, discoursing upon the growth of medical specialisms, during the present generation. He therein points out the advantages of a slow growth and a judicious differentiation, but he is also keenly alive to those disadvantages that must necessarily follow an insecure foundation. He believes in a wide field of study, and a goodly period of time spent in it, before the neophyte is admitted into the ranks of the specialists. The complexity of the human body, and the close correlation of all its finer parts with one another, invite the profession to the formation of specialties, and to form them with a high regard for our undivided economy. Dr. Osler quotes from Plato in this connection:

"Plato must have discussed this very question with his bright friends in the profession—Eryximachus, perhaps—or he could never have put the following words into the mouth of Socrates: 'I dare say that you may have heard eminent physicians say to a patient who comes to them with bad eyes, that they cannot cure his eyes by themselves, but that if his eyes are to be cured, his head must be treated; and then again they say that to think of curing the head alone, and not the rest of the body also, is the height of folly. And arguing in this way they apply their methods to the whole body, and try to treat and heal the whole and the part together. Did you ever observe that this is what they say?' This paragraph embodies the law and the gospel for specialists."

An undesirable result may always be expected when the attempt is made to manufacture a complex construction, with materials that are ill-seasoned, and in too short a space of time. The West Africans have an adage which is pertinent to those who rush so rapidly into the specialties. It says in effect: "An unfortunate spectacle is a blind man traveling on the wrong road, carrying a load of rotten nuts in a bag that is full of holes."

Dr. Osler considers that the incentives to the speedy adoption of a specialty may appear strong ones, and nevertheless be unworthy of acceptance. He says: "The more speedy success that ofttimes comes from the cultivation of a specialty invites young men to early adopt a partial line of work. How infrequently are we consulted by sucklings in our ranks as to the most likely branch in which to succeed; far more frequently are we addressed another way—a student with the brazen assurance that only ignorance can give, announces that he intends to be a gynæcologist or an oculist. No more dangerous members of our profession exist than those born in it, so to speak, as specialists. Without any broad foundation in physiology or pathology, and ignorant of the great processes of disease, no amount of technical skill can hide from the keen eyes of colleagues defects that too often require the arts of the charlatan to hide from the public."

Dr. Osler says to the young would-be specialist that a strong position depends upon a strong foundation, and he holds up the late Sir William Bowman, as the great modern exemplar in specialism, who was so preëminent in several departments that the identity of the physiologist is almost lost in the ophthalmologist.

PHILADELPHIA LETTER.

The most prominent subject of discussion, in all circles, but possessing special features of medical interest during the past week, has been the weather. Although as an ordinary topic of conversation, it has been declared to be "bad form," yet when the temperature gets up to par, or above, comment is justifiable, of course within the usual limits of polite language. Moreover, anything stronger than this would be useless, for if abjurgation of the weather or the weather bureau had the slightest influence upon mean temperature and general humidity, it can be taken for granted that the hot spell would have terminated in a much briefer time than it did. The five days preceding July 26, 1892, will be memorable over a large section of the eastern United States for sustained high temperature, remarkable magnetic disturbances, and thunder storms of almost cyclonic violence. Deaths from lightning were reported at a number of places. On the 23d there was a fine display of the aurora borealis. Cases of sunstroke and heat exhaustion during these few days occurred in our northern cities by hundreds, and scores of deaths were directly or indirectly caused by the heat. The morbific influence, as usual, was strikingly manifest in the greatly increased death-rate, especially among young children. On the 26th of July, the thermometer at the office of the United States Weather Bureau in this city, indicated 100.8° F. The only higher temperature previously recorded at this office was on September 7, 1881, when it went up to 101.5°. These are the highest figures for Philadelphia within fifty years. At the Pennsylvania Hospital the temperature was 102° on the 26th, ult. The number of deaths from all causes up to three o'clock that day (July 26) was 103, and from Saturday noon to Tuesday noon, 350, of which at least 75 were ascribed to the heat, to which might be added 6, which were reported during the next twenty-four hours and many others which remained under treatment. In spite of the fact that the thermometer was undoubtedly higher in this city than in New York or Chicago, the mortality was not correspondingly great for the reason that the laboring portion of the population live in greater comfort here, largely occupying their own houses, they are less crowded and have better ventilated sleeping rooms; not only have they private bath rooms at home, but also have access to public bathing and swimming pools established by the city authorities in the thickly settled portions of the city. Owing to the well supplied markets, the food of the laborer is of better quality and better prepared than in some communities, and there is probably less intemperance. If it be true, as stated, that uncomfortable homes and indigestion from badly cooked food, are the main influences in leading the laborer to alcoholic indulgence, the explanation is at hand for his better social condition here, where, moreover, with the aid of the building society he can buy his own house and start out in his career as a capitalist. All of which has an effect upon the health and vigor of the workman and consequently may appropriately appear in this correspondence; more especially since indulgence in alcohol and depressed vitality are acknowledged predisposing causes of insolation. The Pennsylvania Hospital, and in fact most of our city hospitals where the grounds around the buildings admit, have erected tents on the lawn under the trees for the treatment of victims of the heat, and these have, at times, during the past week, furnished scenes of activity which recalled a field hospital during the war after an engagement, only *minus* the blood. The treatment was mainly refrigerant, the object being to abstract heat as rapidly as possible. The patient, nude, with the exception of a towel across the loins, is rubbed with ice and with a large watering pot showered with ice water, at the same time rubbing the surface to keep up the circulation of the blood. When there is marked determination of blood to the head or internal organs dry cupping is resorted to, and hypodermic injections of small doses of strychnine or cocaine if there is weakness of the circulation. As soon as the temperature has fallen to normal, the patient is rubbed dry and covered with a blanket, and bromides or antipyretics administered according to circumstances. This plan of treatment has been used here for twenty years or more and gives very satisfactory results.

Reference has been just made to the free use of baths in this city; in fact complaint has been recently made that the supply is running low and the householders have been warned against waste of the precious fluid. Although we are now using over 140,000,000 gallons daily, a larger quantity per capita than any other large city, the supply ordinarily is largely in excess. At the rate that we are increasing the demand it is estimated that in less than ten years, we shall need 500,000,000 gallons daily. This city is using nearly as much water now as London, which is four times as large in population. The new Reaborough reservoir adds a capacity of 148 millions to the 869 millions, or a total storage of over 1,017 millions of gallons of water, for which the upper Schuylkill is an abundant supply for the present. To this may be added a variable amount taken principally by private individuals or institutions from deep artesian wells, and as an extra source to large manufacturing establishments in the northeastern part of the city, the Delaware affords a practically inexhaustible quantity. It is estimated, however, that at the present time there is a daily waste of 30 to 40 million gallons, owing largely to leaking attachments in houses, and to the lavish use in washing pavements, which has been forbidden during the present short supply. There will probably be a thorough examination made of the entire system and the general introduction of water meters into private houses is now under consideration.

A new departure has been taken by our city government with regard to sectarian medicine. Mayor Stuart has just signed a bill appointing a corps of homœopathists, consisting of one from each poor district of the city, 25 in all, to share, with the regular physicians previously appointed, the medical care of the city poor. If this act were accompanied by one defining the peculiar characteristics of the homœopathist and compelling him to confine himself to so-called homœopathic practice, some ultimate good might result, to scientific medicine. However much we may commiserate the sick poor who will ask for mica pains with medicine compounded *sec. art.* and receive silica 3x with doubtful milk sugar, we cannot help appreciating the refreshing coolness of the whole procedure just at this particular time. If it would only lead to a fair comparison between the results of treatment of patients by this body of sectarians and patients in similar circumstances having the immense advantage afforded by non-sectarian, scientific physicians, the test would be welcomed by the latter as an object lesson to the community. Some persons, however, are utterly inaccessible to argument or demonstration. Only a short time ago the daily papers reported a disturbance between a certain homœopathic children's hospital in this city and the physicians who did not confine themselves to so-called homœopathic remedies, and when the managers passed a rule that such peculiar remedies should only be used in this hospital, the medical staff resigned in a body rather than obey the law of the institution. Such is modern homœopathy!

To turn to a more profitable subject, it is worth noticing, that Dr. William Duffield Robinson, who for more than ten years has been physician to the Eastern Penitentiary has recently published the results of his analysis of the records of this institution for a period covering sixty years and over 15,000 cases. Taking the records as fairly indicative of the total amount of crime and representative as regards the convictions of criminals of a certain area of the country from which deductions may be justly drawn applicable to some vexed questions in penology, he proceeds to the following conclusions: With regard to the reformation of criminals, he first limits the word "reformed" to the sense of being "neither Christianized nor moralized but that the habit of crime doing has been stopped." He answers that in this sense of the word reformations are frequent. He claims that persons of 60 years of age are about eight times as trustworthy as others only 25 years of age. "Putting this in another way, of eight people who are criminals of the penitentiary grade, 20 to 25 years of age, when they shall have become 60 to 65 years old, seven will have reformed, and only one remain criminal." This has much encouragement in it for philanthropists engaged in this work. His results give little support to the "hardened criminal" idea. It is the young man whose turbulent passions have not been disciplined by experience and punishment, who is the readiest to commit crime. There are, it is true, certain special offenses, to which those more advanced in life seem peculiarly addicted, but their number is small. He finds homicide, forgery, horse stealing and counterfeiting, all showing during the last decade a marked decline. Even robbery and burglary show a falling off and larceny is decreasing in frequency. On the contrary, embezzlement is rapidly increasing and sensual offenses and crimes of personal violence are of more frequent occurrence. Without making further extracts, the following statistics of relative proportion of crimes affords a striking summarization for serious consideration. "Of the total of 15,005 sentences to the Eastern Penitentiary during sixty years, there were for thefts and frauds, including larceny, false pretences, receiving stolen goods, forgery, counterfeiting, robbery, burglary, fraudulent written instruments and the like 77.19 per cent.

"For all personal assaults, including assault and battery in its different forms, mayhem, manslaughter, poisoning and murder, 12.66 per cent.

"For all malicious crimes, including malicious mischief, arson and perjury, 3.05 per cent.

"For all sensual crimes, 5.40 per cent.

"For all breaches of statute law, such as carrying concealed weapons, sending challenges, tramps, illegal voting, illicit *liquor selling and smuggling*,1.16 per cent.

" For felonies and misdemeanors unspecified,1.16 per cent. As showing what proportion of reconvictions occur, we find that the 15,005 sentences represented 12,895 individuals. Of these 9,248 have been convicted once, 2,248 twice, 748 three times,328 four times,148 five times,78 six times,39 seven times, 18,eight times. 20 nine times, 4 ten times, 4 eleven times, 2 twelve times, 3 fourteen times and 1 for each of the remaining numbers of times up to 22."

In the summary issued for the week ending at noon July 30, the total number of deaths in this city were 870, the largest number, it is said, ever reported for a corresponding period. It is estimated that nearly one-half, or over four hundred deaths, were attributable to the excessive heat. In the meteorological summary, issued by Mr. Day, the Local Forecast official, U. S. Weather Bureau, this statement is made with reference to the temperature: "The prominent feature of the month just closed, was the unprecedented 'hot spell,' from the 24th to the 29th inclusive, with maximum temperatures of 91, 93, 101, 96, 96, 98, and daily averages of 82, 84, 88, 87, 86 and 89 degrees." No rain of any amount, excepting on the 14th, fell at this station for twenty-five days, following the 3d of July. On the 30th and 31st, there were several thunder showers, with copious precipitation, thus relieving the threatened water famine. The total rainfall for the month was 2.97 inches; the average for 21 years for July being 4.54 inches, leaving a deficiency, therefore, of 1.56 inches. It may be mentioned as a matter of special interest that the official report contains the further statement that there were no days on which frost occurred during the month.

Dr. W. C. Hollopeter recently reported to the County Medical Society, two interesting cases of " mucous disease; chronic intestinal catarrh, with one autopsy." He expressed surprise that this condition has not received more attention. It should be separated from ordinary chronic intestinal catarrh in children, the literature of which is quite voluminous; the only author who distinctly outlines this particular form being Eustace Smith, who speaks of it as a sequel of whooping cough. Dr. Lewis Star also refers to it in " Diseases of the Digestive Organs in Childhood." The special symptomatic feature is the occurrence of, constipation for several days, followed by profuse mucous discharges containing bacteria and salts, and accompanied by general wasting and tumid, band-shaped abdomen. In the fatal case, the lesions were found limited to the intestines. "The lymph- nodules or solitary follicles of the whole of the colon and part of the small bowel, the ileum, were in an inflammatory condition,and in many there existed deep ulceration." This envolvement of the small bowel is quite rare and is found only when intestinal disease has a protracted cause. Follicular ulceration of the intestine is itself an unusual occurrence and more especially so, when found in the small bowel. The ileum in the case reported had a worm eaten appearance owing to the numerous enlarged and ulcerated nodules. Usually the ulcers were not above 1-6 to 1-4 of an inch except where several had coalesced, they extended through the mucosa in the sub-mucous tissue. The reporter in conclusion called attention to the fact that this disease is separated from ordinary catarrhal inflammation by its clinical course and pathological appearances. The discharges are usually alkaline. The disorder is not necessarily a sequel of whooping cough or a consequence of second dentition, but may occur after any depressing disorder. It is not necessarily incurable. As might be anticipated the strictest attention to diet is required in its treatment conjoined to measures calculated to build up the nutrition of the little patient.

The following real incident carries a moral for those who have the penetration to perceive it. Your correspondent happened to meet socially a gentleman who was subsequently ascertained to be connected in a reportorial capacity with one of our large daily journals. A certain prominent doctor's name was mentioned and the reporter innocently remarked " Oh yes, I know Professor Blank very well. *He* is a great friend of our paper, and whenever he had an interesting surgical operation he used to send us an account for publication." It used to be a matter of conjecture how the papers succeeded in getting reports of operations, but it is now clear that the evidence of enterprise is not all in favor of the daily press.

New York Board of Health; Its Sanitary Superintendent and the Late Advisory Board.

To the Editor of the JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION:

My Dear Sir:—In recent editorials and communications in various medical journals, in relation to certain changes in the New York Board of Health, *it is said that* Drs. Janeway, Jacobi, Prudden and Stephen Smith have resigned their honorary positions on that Board, on the ground that faithful medical employés have been brutally treated at the hands of pot-house politicians, and ordered to hand in their resignations; in other words, that reputable and competent men have been put out of office, without complaint or pretence of charges "for cause." . . . . Dr. Ewing, who has for *twenty* years, been Sanitary Superintendent, was forced out, of the important position, by President Wilson, it is alleged, in order that a politician or a person demanded by a *political organization, might be put in his* place.

They very candidly admit that the above is based on hearsay knowledge. As a matter of right and justice it is well that they do; for with one solitary exception, this whole statement is a malicious invention, without a word of truth in it, from beginning to end.

Drs. Janeway, Prudden, *Jacobi*, and Stephen Smith, *did resign. Drs. Janeway and Smith have both "feathered their* nests" as high officials in this same Board of Health, on high salaries, and with little to do, within the *thirty years*, during which time, it is alleged, "it has not been altogether free from the slime of the political serpent." (Ibid.)

It seems harsh to assume that they resigned, "because, faithful medical employees were brutally entreated to send in their resignations," for this is false. What they resigned for, is their own concern. There were no physicians ordered *to resign* by anyone. *One*, and only *one* was requested *to* hand in his resignation. This was Dr. Ewing, who was *paid* out of the city treasury, *$4,800.00* a year. *He* succeeded *Dr.* Walter F.Day, *four* years ago,not *twenty*,as alleged; and,while trying to fulfil his public duties, carried on an extensive, private practice. His predecessor was not known as a practitioner.

He was requested to surrender his office, not on any "*pretense*," but on an open complaint and charge, *that he did not* visit the Pest-house *on North Brother's* Island.

Dr. Ewing was succeeded,by a gentleman utterly unknown in local politics, who commenced at the "bottom round of the ladder" nine years ago, in the Board of Health, and has by the dint of persevering effort, raised himself to the position which he now occupies, though, with nearly a thousand a year, less than the gentleman whom he succeeds was paid. Who does not know of *Dr. Cyrus* Edson, the present Sanitary Superintendent, as an indefatigable and progressive writer in everything pertaining to sanitary science?

So much for this "tempest in a teapot." In this connection it may be well to have it more generally known, that in this whole country there is no city, in which politics interferes less in sanitary matters, than in New York. *If there* is anyone who can cite a *single* instance in which a member of the medical staff has been removed *on purely* political grounds let him speak out, and I am sure it will be news to New York physicians. Yours respectfully,

TRUTH AND FAIRPLAY.

ORIGINAL ARTICLES.

ACUTE INTESTINAL OBSTRUCTION AND THE USE OF SALINE CATHARTICS FOR DIAGNOSTIC PURPOSES.

Read by Title in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, June, 1892.

BY HENRY H. MUDD, M.D.,
OF ST. LOUIS, MO.

The diagnosis of a chronic intestinal obstruction can usually be determined by its clinical history and its symptoms with sufficient clearness, and in time for definite action. Acute intestinal obstruction is often sudden in its onset and obscure in its symptoms. Destructive local changes occur in a few hours, and grave constitutional complications develop with surprising rapidity.

A severe colic or an acute peritonitis may produce symptoms which strongly suggest intestinal obstruction. The three cardinal symptoms of obstruction of the bowels, nausea, pain and constipation, are present in each one of these three distinct diseases. The three conditions require widely different treatment. The pain and collapse of a severe colic, an obstruction, or of peritonitis, demands immediate relief, and we promptly and unhesitatingly resort to opium for its control. Opium arrests pain, allays vomiting and delays impending collapse. It so mitigates every symptom of colic, peritonitis or obstruction, that the differential diagnosis becomes obscured, and a doubt which paralyzes action is engendered in the mind of the physician.

Every practitioner has witnessed the disastrous effect of the delay that is imposed by this uncertainty. Many of the cases of obstruction, with stomach emptied of its contents, and relieved of pain by the prompt administration of opium, remain quiescent for many hours. The flaccid abdomen, the soft regular pulse, the normal temperature and the absence of tenderness and pain, allay anxiety. The anorexia and indisposition to move about the bed do not determine the condition. Meteorism may be present, but neither its presence nor its absence determine the solution of the problem.

This condition of doubt may exist until very serious local changes have occurred in the strangulated loop, and with but little evidence of change in the general condition, until the final collapse develops suddenly on the fifth or sixth day of the sickness.

It is a clinical fact, too often overlooked, that a very tight constriction of the bowel, one that promptly causes gangrene of the strangulated loop, gives but very little local evidence of its presence. It does not so quickly cause a local peritonitis as does that strangulation which, while preventing fecal movement, only impairs the free circulation of blood, thus promoting engorgement and inflammation, with its attendant pain and tenderness.

The text-books have taught, and the profession has insisted, that a purgative in intestinal obstruction was an unmitigated evil. Indeed, so strong is this feeling that it is almost regarded as criminal to use it where obstruction is suspected. Yet the use of enemas in supposed intestinal obstruction is a very common practice. Enemata are above everything the remedy for the obstruction of a fecal accumulation, but this condition is not usually difficult of diagnosis and is not now under consideration. What do the large fluid injections accomplish in a case of obstruction from other causes? The enema may bring away more or less of the contents of the lower bowel. It arouses a peristalsis unpleasant to the patient and inefficient in its purpose. The enemas hasten the destructive changes at the point of strangulation, and they do not make clear the diagnosis. Its repeated use hastens the final collapse even as a purgative does. Yet the patient submits to and the physician persists in its repeated and continuous use. It is not efficient above the colon except by peristalsis. The danger of a purgative lies in the peristaltic action which it excites. Without it, the patient will frequently, under opium, remain several days with but little peristalsis, though the destructive changes are silently advancing at the point of obstruction. The decomposition going on in the contents of the intestinal canal is rendering the fluid offensive; the sensitiveness of the intestine above the obstruction is increasing, and grave vaso-motor changes are undermining the resisting powers of the individual. When peristalsis is finally aroused by nature's forces in spite of opium, and just as the diagnosis becomes clear, the patient succumbs, and dies in spite of operative interference, which is then urgently demanded by the patient and the attending physician.

How can we solve the doubt and make a positive diagnosis in time to act efficiently and save the patient? This is the problem. I believe the much abused purgative will help us in the early diagnosis, if used properly and at the right time. I think we may assume that:

First: There is legitimate reason for the most skilled diagnostician to be in doubt in some cases of intestinal obstruction.

Second: The differential diagnosis rests ordinarily between colic, peritonitis and obstruction.

Third: Laparotomy is accepted as the most reliable therapeutic measure for the relief of intestinal obstruction.

Fourth: Laparotomy, to be a good therapeutic agent, must be performed early in the existence of the obstruction.

Pain, vomiting and constipation are the three cardinal symptoms of obstruction; yet these conditions are present in constipation, in intestinal colic, and in many diverse conditions.

What are the effects of a saline cathartic on the three conditions above mentioned, viz.: colic, peritonitis and intestinal obstruction?

Colic: It will purge a case of colic, and a sedative then cures it.

Peritonitis: It may arrest a peritonitis.

Obstruction: It will develop and make plain the more serious condition of a mechanical obstruction. If given early in the case, the distress and aggravation of the symptoms which it arouses will subside under the use of morphine, and the general condition will then permit operative relief.

It is only where the doubt is sufficiently strong to control action that the saline purgative is used. It should be promptly given. The time for its efficient administration is in the lull or quiet induced by the first dose of morphine. It may again arouse ineffective and painful peristalsis, but it will in many cases resolve doubt and determine surgical interference when it is still possible to save the patient.

If the diagnosis of obstruction is clear, there is no excuse for a purgative. No one would attempt to relieve an intussusception, a hernia, a volvulus or a stricture by a purgative. They aggravate and make more urgent every symptom which attends the condition. Yet this is a good reason to administer a saline cathartic in the beginning of many doubtful cases as a diagnostic measure.

A purgative in intestinal obstruction is an unmitigated evil in its effects upon the strangulated loop and the patient. It should not be given unless it is for the benefit of the surgeon and to purge our minds of doubt. But it seems to me that the great uniformity with which cases recover from the primary depression and collapse which so frequently announces the onset of intestinal obstruction, indicates to us the possibility of using *a purgative* as a diagnostic agent rather than an exploratory laparotomy in the earlier hours of the disease. If the peristalsis which inevitably sooner or later declares itself, and convinces the most skeptical patient and the most obtuse physician that the obstruction is pronounced and absolute, is promptly aroused by a saline cathartic given before the destructive changes have occurred, and before the vitality of the patient has been exhausted, the action thus aroused will again subside under the use of opium (morphine), and the depression which is occasioned by its use will disappear, leaving an open field for the surgeon.

Laparotomy has rapidly grown in favor as the most reliable therapeutic measure for the relief of intestinal obstruction, if resorted to early in its existence. Surgeons sometimes conceal their ignorance by "explorative laparotomy." Exploratory laparotomy, where symptoms of intestinal obstruction are present, may lead to the prompt recognition of the condition and its cure; but it is a dangerous proceeding where meteorism is present, circulation feeble and inflammation already existent. These conditions may exist without mechanical obstruction and without the existence of a condition amenable to operative measures. I believe we can avoid some of these useless operations, and save many patients, by promptly resorting to the less dangerous saline cathartic. It will be admitted when laparotomy would not be considered. It will eliminate doubt, and enable the physician and surgeon to intelligently urge a prompt resort to the efficient treatment necessary to relieve an obstruction, viz.: laparotomy.

If it has been determined to perform laparotomy the cathartic is of course not to be considered. If however, there is a case anxiously and carefully considered for twenty-four hours (an arbitrary but no a standard time), and grave doubt is still presen concerning the condition, an efficient saline catharti (Epsom salts), followed by an enema, may solve the doubt. It should be remembered that the saline cathartics are dependent upon a fair amount of fluids in the body for their efficient action, and if they are given after a patient has been for a number of days without imbibing fluids, they will not act. The paralysis which attends intestinal inflammation will also interfere with their action.

Will you, in a doubtful case, if presented within forty-eight hours of the onset of the trouble, wait and let time resolve the doubt and destroy your patient, or make an exploratory laparotomy on a patient who does not need it? It appears to me that a purgative is the third and safest method of solving the doubt.

The free, spontaneous action which follows relief from an obstruction, whether by nature's unaided effort or by surgical interference, not infrequently produces such a collapse that death follows. Death may be precipitated by cathartics if used when obstruction has existed for any length of time, but it cannot be said that they cause it, for the obstruction surely determines conditions which finally excite the peristalsis, collapse and death, and the longer the peristaltic action is delayed the more dangerous it is.

Intestinal obstruction may exist for days without developing any more positive signs of its presence than we frequently see in obstinate constipation with its attendant pain, sick stomach, meteorism and prostration. It is for these doubtful cases that I urge as a conservative measure the administration of a saline cathartic. I am sure the modern physician will admit that there is legitimate reason for doubt in the diagnosis of at least a small percentage of cases of intestinal obstruction in the early stages of their development.

ON THE TREATMENT OF INJURIES OF THE ABDOMEN NOT REQUIRING SURGICAL OPERATIONS.

Read in the Section of Surgery and Anatomy, at the Forty-third annual meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY J. SCHNECK, M.D.,
OF MT. CARMEL, ILL.

In practice the stubborn facts are daily demonstrated that the prognosis of wounds of the abdomen is very unfavorable, the diagnosis frequently obscure or recondite, and the results of treatment often unsatisfactory; especially so in the hands of the general practitioner. Hence, any account which gives the results of experience must be of interest to the profession, even if not of much value in itself. It is easy enough to theoretically draw the line between operable and non-operable cases in abdominal injuries, but in practice it is often the most difficult question to decide in the whole domain of surgery; especially where there are no external wounds or bruises to serve as guides.

The well established fact, accepted by surgical authorities of all ages, *that the peritoneum is especially prone to become inflamed when it is lacerated,* bruised or disturbed, or the ease with which an inflammation extends to it from neighboring organs, should never be lost sight of. If there is laceration r displacement of any of the important organs, it may be necessary, or the positive duty, to perform parotomy and adjust the rent or displacement at nce.

For purposes of study, injuries of the abdomen may be divided into four classes:

1. Injuries involving the parietes only, in which he integument remains unbroken.
2. Injuries in which the integument is unbroken, ut some of the internal viscera are involved in the njury.
3. Injuries in which there is a solution of continity involving the parietes only.
4. Injuries in which there is an open wound in the arietes and the internal viscera are also involved.

The last two of these classes may be dismissed at nce from consideration in this paper, as their treatment is by operative means from the beginning.

In injuries involving the parietes only, there may be extensive infiltration of the cellular tissues; the principal symptoms in such cases are pain, soreness, welling and ecchymosis, and a doughy, crackling ensation on palpation. In other cases there is an ccumulation of blood between the muscular layers; n these cases there will be more or less pain, soreness, and a swelling which will impart a spongy senation to the examining finger. In another class of ases there is rupture of some of the muscular fibres, when there will be severe pain and soreness to the ouch, which is greatly aggravated by motion, and, if he tear is extensive, an inability to stand erect, without support. The examining finger will detect a more or less abrupt indentation; or only a soft, non-resisting condition over the site of the injury.

Although these cases may appear simple, the prognosis should be guarded; the most serious consequences may follow an apparently slight injury. The treatment should be thorough and careful. Inflammation may extend to the peritoneum, this must be looked for and guarded against. Suppuration may follow with extensive burrowing of pus, when it will be necessary to make a free incision and wash out the pus cavity.

In extensive rupture of the muscular tissues recovery will be slow and may be followed by more or less permanent pain and weakness of the muscles, and finally a hernia. These ruptures are usually produced by sudden violent efforts, as in falls, lifting or gymnastic exercises, etc. The treatment of these cases is the same as that for the second class, which will be given further on.

We now come to the second class, or injuries in which the integument is unbroken, but some of the abdominal viscera are involved. Here the practitioner of surgery finds himself confronted by one of the most trying circumstances in the whole range of practice.

The abdominal cavity contains more viscera with dissimilar functions than any other cavity in the human body; hence, an injury to this part of the body will produce a great variety of symptoms. Before an intelligent line of treatment can be instituted it is necessary to decide, if possible, the exact nature and extent of the injury.

Probably one of the most common sources of danger in injuries of the abdomen is shock produced by bruising or otherwise injuring the abdominal nerve centers. The epigastric or solar plexus supplies all the viscera in the abdominal cavity. It receives all the fibres of the great splanchnic nerve, part of those of the lesser splanchnic nerves; also the terminal branches of the right pneumogastric nerve. The semi-lunar ganglia are part of the solar plexus; they receive the great splanchnic nerve, the origin of which is from the lower thoracic ganglia. Each of the thoracic ganglia is connected to the nearest anterior root of the spinal nerve; and the skin of the epigastrium is supplied by these very same spinal nerves, viz., from the fourth to the seventh intercostal nerves. There is therefore a complete nervous circuit from the mucous membrane of the stomach and intestines to the skin of the epigastrium.

Having thus in mind the innervation of the abdomen, we can more rationally explain the cause of the serious symptoms which follow an apparently trivial injury of this part of the body.

When called to treat a patient who has received an injury of the abdomen, it is necessary to discover if possible, the nature and extent of the damage done. Is there only contusion of the parietes and viscera or are some of the internal organs ruptured or dislocated, and if there is an organic lesion, is it of such a nature as to require an operation? There may be rupture of the diaphragm, stomach, intestines, liver, bile duct, spleen, pancreas, supra-renal capsule, kidneys, ureter or the bladder. Or these several organs may be more or less bruised or displaced. While there are few, if any, pathognomonic signs for any of these lesions, yet the most of them may be detected or very strongly suspected if all the symptoms in any given case are carefully investigated.

There may be serious nerve disturbance from simple contusions of the abdominal parietes, but usually when there is profound shock following an injury in this region, it is tolerably safe to conclude that there is more or less damage done to the viscera, not necessarily of the nature of an organic lesion, however. When there is excessive pain, rapid weak pulse, great restlessness and anxiety, persistent vomiting, catchy, spasmodic respiration, with a feeling on the part of the patient that he is dying, or if there is delirium, or unconsciousness, one may safely suspect that some of the internal viscera are seriously damaged. While collapse is a common occurrence after abdominal injuries, yet cases in which there was so serious an injury as rupture of the liver or intestines have been known to happen without being immediately followed by this symptom. When shock is of short duration there is a reasonable probability that there is no serious internal injury. In collapse from nervous shock following an injury of the abdomen, in which there is little hæmorrhage, the skin is usually cyanosed, cold and clammy; while in serious internal hæmorrhage the skin is pale, cold and with less moisture.

Persistent vomiting is an indication of severe shock or serious disturbance of some of the internal organs; when blood is vomited the injury is probably of the stomach. Pain is often an uncertain diagnostic guide, while localized tenderness is usually of great value. Experience shows that injuries received above the umbilicus are more frequently serious or fatal than in those where the injury is below that point. This is due to the fact that more of the important organs are located above that point than below it. In the act of respiration there is also more disturbance of the parts in the upper portion of the abdomen. Valuable information may often be obtained by a close inquiry as to how and by what the injury was done; and the position and condition of the patient; if a heavy wheel or roller has passed over the body, or if the body has been caught between two heavy moving bodies, there is a greater probability of rupture of some of the internal organs or blood vessels than if he was struck while standing free; or had fallen against an object.

The shape of the impinging body will often serve as a help in deciding the amount and kind of injury done. The thickness of the abdominal walls should also be taken into the account; if they are thick and fleshy they will offer a considerable protection to the internal viscera. Shortly after a meal when the stomach is full it is more readily ruptured than when empty. So with the bladder, it is more readily ruptured when it is full; in this condition it also rises higher in the pelvis and is thus more exposed. The following are the principal symptoms usually found when the several organs are severely injured. In rupture of the diaphragm the most prominent symptom is an unsatiable thirst. In the case of a large man who fell from a train while it was passing over a high trestle there was constant craving for water, quick superficial respiration. He died on the third day; there was a rent 2½ inches long in the diaphragm on the left side, the peritoneum congested and the right thigh was fractured. I have been unable to find reports of instances in which the diaphragm was sewed up after such injury. Spontaneous unions are not rare but are usually followed by phrenic herniæ. In rupture of the stomach there is usually profound shock, vomiting of blood and a constant, severe, radiating pain from the seat of injury; recovery has taken place, without an operation when the rent was small. In laceration of the intestines there is meteorism, pain of abdomen and great tenderness; the muscles are rigid and unyielding to the touch; breathing is short and thoracic; countenance expressive of distress and anxiety; vomiting early and severe; thirst and profound shock; unless the rent is small death will follow, laparotomy is usually the only hope.

Rupture of the liver is usually followed by jaundice and itching of the skin; white stools and saccharine diabetes: pain and tenderness over the region of the liver. Patients have recovered from extensive injuries of this organ without operative treatment. When the bile-duct is ruptured there is usually severe pain in the hypo-gastric region, great anxiety and restlessness followed by collapse; this usually terminates fatally. The principal symptom in rupture of the spleen is rapid and profound collapse, produced by the violent hæmorrhage which usually accompanies this injury; the pain is located in the left hypochondriac region. Recoveries have taken place, after rupture of this organ, without surgical aid.

There are no symptoms recorded in injuries of the pancreas which would be of any diagnostic value. There is not much hæmorrhage, and severe injuries are not necessarily fatal. The peritoneum is thin and readily ruptured when put on the stretch; in such cases there is great tenderness over the whole abdomen, pulse very rapid and small, excessive tympanitis; the lower limbs are drawn up, and the upper portion of the body bent forward.

In rupture of a kidney there is vomiting, some collapse, pain along the course of the ureter and in the lumbar region; retracted testicle and pain along the spermatic cord; a constant desire to urinate, but often an inability to do so; the urine is usually bloody and scanty. In a railroad injury in which the right kidney was ruptured and the right foot mangled, there was, throughout the four days the patient lived, numbness of both thighs. Rupture of the kidneys is not necessarily fatal, especially if the injury is on its posterior surface. Opium should be given cautiously in injuries of these organs.

When a ureter is torn there is not usually any very serious symptoms immediately following; but in the course of a few weeks a large tumor will develop on the affected side; this when tapped will prove to be caused by an accumulation of urine, blood and probably pus.

When the bladder has been ruptured there will be a constant desire to urinate; the urine is usually scanty and bloody; pain about the pelvis excessive; patient is unable to stand or walk.

Out of 200 cases tabulated by Rivington but 8 recovered. Operative measures appear to offer the best hope of success.

In rupture of a large blood vessel collapse does not usually follow immediately on receipt of the injury; the patient often being able to walk some distance before exhaustion is produced from the excessive hæmorrhage. In internal hæmorrhage collapse is often a means of temporarily checking the hæmorrhage.

The surgeon usually finds the patient in a state of cardiac depression and shock with nausea, vomiting, pain, restlessness, cold extremities, shrunken condition of the skin and clammy perspiration. The abdominal muscles are in a state of tonic contraction. It is important to note that this inhibiting condition extends frequently to the muscular coats of the intestines and sometimes to the urethra and ureters; for in many cases there is suppression of urine and obstinate constipation of the bowels. This condition may continue from a few hours to several days. If the patient survives this condition or is relieved by artificial means then there follows a stage of reaction and probably inflammation. If the inhibited condition is not relieved the patient usually dies in this stage of shock. So that the first important object to be accomplished is to restore the innervation to its normal condition. This is best accomplished by external and internal warmth. Stimulants by the stomach frequently are of no avail, from the fact that they are not assimilated; in such instances they are best given hypodermatically. Brandy, nux vomica and digitalis are usually the most available and may be administered either way. Draughts of hot water are also of much value, even if vomited. Hot applications, to the extremities, of mustard draughts or flannel cloths wrung out of a strong solution of capsicum are valuable restoratives. As stated in the foregoing pages, in many of these cases there is a firmly contracted condition of the muscular coats of the bowels causing obstinate obstruction. It is surprising in how short a time the contents of the intestines will become hard and dry after an injury to this region. In many cases the state of collapse will not yield until this source of irritation is relieved. I hope to illustrate by the following cases how rapidly such cases will recover from shock after the bowels have been cleared of their hardened contents by hot water injections. The hot water serves a two fold purpose; it clears away the hardened and dried feces and thus removes a future source of irritation and infection; the hot water also is a direct stimulant to the nerve endings in the intestines. The injection should be used as soon as possible after the receipt of the injury. The rationale of this treatment will be readily understood if we call to mind the position of the solar plexus with its numerous satellite plexuses. To illustrate the results of this method of treatment I will report briefly three cases; selected so as to show the different methods of injury by which such cases occur.

In August, 1883, I was called to see R. W., a farmer, who had been struck by one limb of an A-shaped harrow, which he was trying to lift over a stump while the horses were dragging it over the ground; the principal injury being received between the crest of the ilium and the lower ribs, on the left side, and extending across the abdomen. I saw him twenty hours after the injury had been received. His face was pale and the features pinched; the whole surface and extremities cold and clammy; pulse barely perceptible at the wrist; abdominal walls were hard and contracted, but slightly distended. He was very restless, writhing and twisting over the bed, and complaining of severe pain in the abdomen. He had not had a discharge from his bowels or bladder since he had received the injury. After administering some palliative remedies, I introduced a catheter and drew off several pints of bloody urine. The pain and restlessness still continued. He was then given a large injection of hot water, which brought away a large quantity of dry, hard nodules of feces. This was repeated several times with like effects. He gradually rallied from the collapsed condition and made a good recovery. Within a year chronic Bright's disease developed, from which he finally died.

In September, 1884, I saw in consultation M. W., a carpenter. Thirty hours before, he had received an injury of the abdomen by making a misstep while walking on an uncovered joist in the second floor of a building; the principal force of the blow taking effect over the region of the umbilicus. I found him in an advanced stage of collapse, in spite of stimulants and external warmth, which had been freely employed. The abdominal walls were very hard and retracted. He had not had an evacuation of the bowels since the injury had been received; the kidneys had acted freely. I advised enemas of hot water, which resulted finally in free evacuations of dry, hard stools. He shortly afterwards rallied, and finally recovered.

In November, 1883, I was called to see F. F., a brakeman, who twelve hours before had been caught between the tender of an engine and a freight car He had sustained a severe squeeze; the principal force being exerted over the abdominal region below the umbilicus. When I first saw him he was not suffering from localized pain, but was very restless; temperature normal; abdomen not swollen, but the walls were hard and rigid. He had not urinated nor had an evacuation of the bowels since the injury. Pulse was not seriously depressed. I drew off the urine with a catheter and administered a saline cathartic, and gave him anodyne remedies. But the restlessness continued and finally developed into unconscious delirium, so severe that it required two men to hold him on the bed. Several doses of the cathartic remedy failed to produce the desired effect, so an enema was ordered. Diligent efforts by this method brought away several large evacuations of hard, lumpy stools, after which consciousness was restored, the restlessness subsided and the rigid condition of the abdomen gave way. For nearly one week the urine had to be drawn off with the catheter. The abdomen became tender and tympanitic from localized inflammation of some of the abdominal organs. At the end of ten days the symptoms subsided, and the patient finally made a good recovery.

The patient having been restored from the shock and collapse, our next duty is to combat inflammation and support the system. Rest is of first importance, and should be continued until all traces of inflammation have been subdued. Many patients have been lost by a neglect of this simple precaution. The following case will serve as a striking illustration of this point:

In September, 1887, I was called in consultation to see R. W., a carpenter, who had fallen on to the flange of a car wheel, while he was carrying a heavy load, striking himself on the right lower quarter of the abdomen with considerable force. He continued to work that day and the next, but felt considerable soreness and pain over the seat of injury. The second and third days he suffered still more severely, so that he did not attempt to work, but was up and about most of the time. On the fourth day the pain was so severe that he was confined to bed; on the fifth day, being still worse, he called in a physician, who found him with a slight fever, abdomen distended and very tender, pulse quick and thready. In spite of careful treatment these symptoms grew more severe until the eleventh day, when I first saw him. He was then in a state of collapse, and died several hours later. A post-mortem examination was made the next day. The major portion of the peritoneum and intestines showed evidences of inflammation, and in the lower and right portion of the abdomen they were extensively gangrenous.

I regard this as a very instructive case. There is good reason for believing that had this man taken rest, and some proper treatment, during the first days after the injury, he would not have developed any serious symptoms. This case also illustrates another important fact: that a severe localized inflammation may run to a fatal termination without the fever ever reaching a high point. The fever in this case never reached above 102°. Is it not probable that the injury to the nerve ganglia, in these cases, is so great that the system virtually never recovers its natural tonicity?

In combating inflammation, it is important to keep the patient cool and quiet; the dorsal position is the best, with the head and shoulders elevated and the lower limbs flexed, so as to relax the abdominal muscles. Next in importance, and to aid in keeping the patient quiet, is opium; it should be pushed until pain is relieved and quiet restored. With the opium give $\frac{1}{10}$ gr. doses of calomel from the beginning; it will keep the portal circulation, which collects the venous blood from the viscera of digestion, active, and thus relieve congestion of the stomach and intestinal canal, and its accompanying glands. Instead of calomel, small doses of sulphate of magnesia may be given, but not to catharsis. When the fever is very high with a full, sustained pulse, aconite in small and frequently repeated doses should be given during the first few days. Locally, leeches may be applied over the point of greatest tenderness and extravasation. Fomentations of flannel sacks filled with hops, steamed until they are hot and damp, then applied constantly over the whole abdominal surface, will relieve pain and soreness, and serve as a restorative. If the warm applications are ungrateful to the patient, poultices made of ice and linseed meal may be used; but usually the former is the best.

The diet should be spare, liquid, easily digested and given cool. Milk is usually the best; blanc mange, custard, lemon sherbet, ice-cream and gelatine are all good. It is important to keep the bladder well emptied, and if necessary use the catheter every four to six hours. In nearly all cases of injury of the abdomen the urine will contain pus in the course of a few days; this should be detected by microscopic examinations of the urine, and when present, I know of no remedy so beneficial as salicylic acid, given about every four hours in 5 gr. doses. Throughout the treatment the surgeon should be very guarded in his prognosis, and exceedingly careful and thorough in his treatment. Every injury should be treated as if it were serious from the beginning to the end.

Dr. Mordecai Price, of Philadelphia, being absent, his paper on "Emergency Work in Abdominal Surgery" was read by title, and Dr. John L. Link, of Terre Haute, Ind., occupied the time allotted to the paper in a discussion on emergency work. He said a wound should be probed as far as the probe will go, and the knife should follow as far as the probe went. Physicians should be held strictly responsible for not operating in cases of injury to the abdomen. Even if he takes an ordinary needle and thread and sews up the wound, it is better than to leave it alone. He reported a case of operation on a dog in which he put in stitches of ordinary cotton, and the dog recovered. The coarse thread sets up an inflammation which causes the neighboring parts to adhere and close the wound.

Dr. Halley, of Missouri, wanted to know if he did nothing to render the thread antiseptic, and received a reply in the negative.

Dr. Quimby, of New Jersey, thought that by following the wound made by a sharp, narrow instrument, with the knife, the operation would be worse than the original wound.

Dr. Senn, of Chicago, was of the opinion that operations should be thoroughly done or not at all. To illustrate his point he reported a case in which a young man was shot through the abdomen. Two very respectable physicians were called, and they, having heard of the new treatment in cases of this kind, viz.: to follow the track of the bullet, opened the abdomen, inspected the intestinal coils and adjacent viscera, and finding no injury to them, closed the wound. The patient, who never rallied from the operation, died in twenty-four hours, and the autopsy revealed more than one perforation. He believed this kind of teaching to be exceedingly injurious to our profession, and only when we can satisfy ourselves that the injury will necessarily prove fatal, should we add the additional risk of operation.

Dr. Halley, of Missouri, said that every one who operates to-day must do so with careful aseptic and antiseptic precautions, therefore every surgeon who does an operation without these safeguards is little better than a murderer. Many a perforation of the intestinal canal will recover if left alone.

Dr. Link said he believed in all the preparation spoken of, but also believed that more cases would recover with operation than without.

The paper on "The Present State of the Surgery of the Vermiform Appendix," by Dr. J. A. Wyeth, of New York, was read by title. Dr. Milligan, of New York, occupied the time in reporting a case of undescended testes associated with hernia operated on by Baccini's method. His remarks were illustrated by diagrams.

HERNIÆ, OPERATIVE AND NON-OPERATIVE.

Read in the Section of Surgery and Anatomy, at the Forty third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY THOMAS H. MANLEY, A.M., M.D.,
OF NEW YORK.

As hernial protrusions through the lower abdomen are a very common infirmity in the civilized human being; and as they are always a source of inconvenience and discomfort, besides being an occasional danger to life, surgeons have, since the earliest times, actively occupied themselves, with a most commendable zeal, in divers expedients to effect a radical cure of them, or to place them in such a position as will conduce to the greatest comfort. Every sort of mechanical expedient has been resorted to for their cure, by traveling charlatans and eminent operators; at one time resorting to castration, at another to vitriol and caustics, the potential and others, the steel clamp, suture of gold, invagination, etc.

Paul Ségond,[1] in his valuable treatise on hernia, informs us that for several past centuries, from time to time, operations for the radical cure of hernia have attained considerable popularity; but they have fallen into ill-repute and been condemned, to be again revived. From the graphic description which Ségond gives us, we can see that the methods and technique of operation in bygone times were manifold and varied, and that so thoroughly and completely have the ancients gone over the field, that but little remained for the moderns to improve on. Hence we see that the vast majority of certain modern hernial operations, bearing the names of various surgeons, are not new at all, but have each and all, with few exceptions, been performed many centuries since. The cardinal object in view, in all cases and at all times, has been the same. The characteristic of the attitude of surgeons towards hernial operations, has been towards extremes.

As recently as twenty years ago, but few, if any, operations for hernia were countenanced or permitted, except in cases of strangulation. Now, the opposite practice prevails. Not here in America alone, but in all the principal countries of Europe, every sort of visceral protrusion through the crural or inguinal rings is, by many, regarded as appropriate for active, surgical intervention.

But no operation yet devised will always prove permanently curative, in any class of cases. Surgical methods, however, will nevertheless, in a certain proportion, cure the hernia. In some it may effect no improvement, and in certain varieties, the mortality following operations on them is very great, regardless of what skill may be employed.

With a view of reaching the middle ground and defining those cases in which surgical operation may seem permissible, and describing those cases in which we should decline the application of sanguineous measures, these notes are submitted to the consideration of my professional brethren.

A Few General Considerations on Operative Herniæ.—There are certain conditions which should not be lost sight of, in all hernial operations, regardless of whether they are hospital or private cases.

To commence, we should have a thorough familiarity with what might be designated the *natural history* of hernia; its complications and almost infinite varieties; what we may look for by Nature's unaided powers, and what may be accomplished by a tentative therapy, in effecting a cure or placing the hernia in a comfortable position. Before a thought of cutting should enter our minds, in hernial cases, we should weigh well the consequences; not the immediate only, but the remote as well. Without question, in a considerable number of cases in which relapse occurs after operation, the hernia may become more painful and unmanageable than it was before anything was attempted, in the way of a radical cure.

Hence, we should, before resorting to radical methods, consider carefully the possibility of relapse, and likewise warn our patients of its possibility. Much will depend on the class of patients which we will have to deal with, for the permanency of cure, will in a large measure depend on the intelligence and disposition of the patient.

But, as has been stated, many herniæ will relapse in a considerable proportion, regardless of what operation may have been employed. Indeed, Dr. W. T. Bull, of New York, at a recent meeting of the American Surgical Society, showed by an elaborate array of figures, that the recurrence of the protrusion is so general, after surgical interference, that the employment of the term *operation for "radical cure"* should be abandoned altogether. And the distinguished French surgeon, M. Paul Ségond, in his work printed ten years ago, put great stress on the fact that any of the operations might kill—*peut tuer*—and that none, of any description whatever, is ever a justifiable procedure in herniæ, "except those in which the dangers from delay are in direct proportion to those entailed by surgical intervention, and then only when all other expedients have failed."

---

[1] Cure Radicale des Hernies, Traité.

Félizét,[2] on the other hand, is an ardent advocate of operation in hernia; yet he does not hesitate to openly avow it, that the surgeon should never permit himself to be swayed, in these cases, except through humane impulses. "While," he says, "anæsthetics have rendered the most tedious and formidable operations painless, and rigorous antisepsis has rendered septic infection impossible, yet neither has changed the morale of our art, and hence the scalpel should not be taken up, except in those, on whom palliative measures have proven useless and the hernia becomes progressively worse with the advance of age."

As all herniæ operated on, in which the patient survives, are invariably radically cured, and quite a number remain so during life, to the great comfort of the formerly afflicted, it seems absurd to ask us to disregard the evidence of our own senses.

No sort of operation known in surgery can, or has, ever perfectly reconstructed anything. We *cure* a man of a dislocation, a fracture, a fistula or a stricture. But have we removed the causes which led to those mechanical and pathological conditions, or have we been able to restore anything like perfection?

Any one who has ever carefully dissected the inguinal or crural structures in a hernia, of any age, will always, on a critical examination, discover a defective development, a want of symmetry and uniformity, in those anatomical structures which support the abdominal contents. Hence, he who pretends that any sort of operative measure, no matter how skilfully performed, will ever accomplish more than improve the herniated condition by confining the viscera above, or so placing them that they will occasion but a minimum of future trouble, trespasses too far on the credulity of his professional brethren, and gives utterance to what is not strictly true.

The radical cure of hernia, then, is an accomplished fact, and must remain, with the same qualifications as when the words radical cure are employed in any other surgical operation.

The operation, another says, "may kill." Very true—and so may the simple scarification of the arm for vaccination give rise to mortal gangrene or tetanus. The extraction of a tooth may be followed by instant death or a dangerous hæmorrhage.

Dr. W. T. Bull, in the essay alluded to, in speaking on the dangers of the operation, says, "the mortality is practically *nil.*

It is interesting to note the present attitude of M. Paul Ségond, as compared with that which he occupied ten years ago, when his invaluable contribution on hernia in general, was published. Then, strongly opposing hernial operation, and conceding an operation with a view of effecting a cure of hernia seldom justifiable, except in special cases; now, after a lapse of ten years, he says: "I regard the operation for the radical cure of hernia an excellent one and frequently perform it for every species of the deformity." (De La Valeur De La Cure Radicale Des Hernias au Point de Vue Du Résultát Définatif.—Congrès Francais de Chirurgie, 1890.)

That the operation for the radical cure of hernia has attained for itself a legitimate position in the field of surgery is best proven by the fact that to-day, in every civilized country of the world, it is being performed on a large scale and in the vast majority of cases, with the most gratifying results. However, with this as with any other surgical operation, it has its limitations. In properly selected cases, it is an inestimable boon, excelled by no other in mechanical therapeutics; while in many others, it is little better than a barberous mutilation, which leaves the patient very much worse off after it than if nothing whatever had been done, or even destroys life. It would not then, in any sense, be regarded a cure-all, but only an expedient, which should be employed, only when other simpler, safer and easier methods fail.

Where must the line be drawn, between the selected and the rejected; those which are appropriate subjects, and those which are not?

In order to answer this question, it becomes necessary to first consider the different varieties of hernial disease; those which are spontaneously curable; those which may be supported by the bandage, and those which, with the advance of time, not only become more painful and uncomfortable, but are likewise more prone to strangulation. We must also examine into a diversity of factors of an etiolgical, anatomical and clinical character. Accordingly it becomes necessary, for convenience of description, to group and classify the cases.

1. Hernia in early life, under the tenth year.
2. Hernia in advanced age.
3. Male hernia.
4. Female hernia.
5. Congenital hernia, proper.
6. Acquired hernia, so-called.
7. Laparotomy-hernia.
8. Hernia in those suffering from constitutional disease.

Regional Division:—

1. Complete inguinal hernia.
2. Incomplete inguinal hernia.
3. Inguinal hernia in female.
4. Crural hernia in female.
5. Crural hernia in male.
6. Umbilical hernia in female.
7. Umbilical hernia in male.
8. Ventral hernia in both sexes.
9. Obturator, lumbar and perineal.

Division on a Basis of their morbid Anatomy and Pathology:—

1. Simple hernia, in general.
2. Incarcerated hernia.
3. Strangulated.
4. Enterocele.
5. Epiplocele or entero-epiplocele.
6. Hernia complicated by pathological changes in contigious parts.

Infantile hernia is very common, either of the umbilical or inguinal typlo. With the male infant it is, no doubt, attributable either to a maldescent of the testes, to phymosis, or to a partial atresia of the urethra.

In ectopic-testis, the organ, as it passes through the inguinal portals, the openings which its pressure effects, often carries with it a fringe of omentum. It may even cause adhesions with a coil of intestine, and lodge it in the scrotum. When neither of these mishaps occur, it may descend late, in intra-uterine life, so that the funicular process of the peritoneum or the rings have not completely closed; and, in consequence, we may have the congenital hernia of the anatomists, or a protrusion through the fascia-propria-abdominalis, complete or incomplete. Besides, we sometimes meet with a spasmodic condition of the cremaster muscle, or the gubernaculum, which might be aptly termed the *flitting testis.* "Now we have it, and now we haven't." A remarkable case of this description was once sent to me for operation, in a child two years old. On the left side, he had an ectopic-testis. At one time we would find the testis in the perineum; then in the scrotum, or in the inguinal canal. And, again, what seemed most extraordinary, it would disappear altogether, mounting out of sight into the abdominal cavity, to appear again, in a day or two, outside the rings. Everyone knows that when the testis is permanently arrested on its way downward, that the presence of a hernia is almost invariable.

---

[2] Félizét, Cure Rad. des Herniæs Particuliarement ches les Enfants, p. 12.

True umbilical herniæ are quite common in babies, particularly females, during the first year. When the naval aperture fails to close in promptly after delivery, then rupture appears. There may be an excess of abdominal viscera, or the clothing is badly adjusted. Indeed, the cause of this parting of the umbilical scar doesn't always appear by any means clear in infancy. There do not seem to be any cases on record, of death from this sort of ventral protrusion in infants, nor evidence that the general health suffers in consequence of it.

The vast majority of cases of hernia in infancy, disappear of themselves by tentative measures, by the use of the bandage or truss; with restriction in physical exercise, proper clothing and dieting, before the tenth year; though later in life the majority of them will relapse again at varying intervals, after maturity. But there is a considerable number of these hernia which are rather aggravated than benefited by the retentive apparatuses; their pressure setting up an inflammation which extends down the sac, with the spermatic cord, or causes a fusion of the projected viscera, when thereafter, their return becomes an impossibility.

With umbilical hernia of the kind considered, it is seldom, if ever, that any sort of surgical intervention should be permitted, for they are usually by simple means, readily and permanently cured.

My own experience has convinced me, that every case of hernia in the child associated with ectopic-testis should be operated on promptly, for its radical cure. It goes without saying, that in infantile inguinal hernia in the male or female, a very careful examination should be always made; and when we suspect that the bladder, ovary, or uterus has left its normal moorings and passed out of the abdomen, an operation is imperative, either for their excision, or return to their normal abode. Dr. O. P. Barber, of Saginaw, Michigan, last year reported a case in which he encountered the uterus in a hernial sac when operating, (*Am. Jour. Gynecology*, Oct., 1891) and Boyer cites cases in which the herniated uterus has become the seat of pregnancy, the living infant being delivered through a large gash, made through the walls of the strayed uterus. He mentions also, several cases of large vesical calculi having been removed from the bladder, when in the same situation (*Malad. Chirurg.*, tome iv, page 207). A young lady has come under my observation who had been an invalid since her menstrual period. After an enlarged, inflamed, herniated ovary, which had been lodged in the canal-of-Nuck was removed, she promptly recovered perfect health. In any case these complicating factors discovered, require prompt surgical relief, the earlier the better.

When a truss cannot be comfortably worn, or when it fails and we have an incoercible hernia, unless the child will submit to long confinement in bed with a proper and systematic dieting, the question of dealing with the case by radical measures arises. In every case, however, we should endeavor as far as possible, to remove the exciting cause; we should perform a circumcision, free the urethra, or rectum, and adopt the simple prophylactic and curative expedient, which has been recommended by Dr. Frank Parsons, of Boston, in these cases, viz.: in all cases of infantile hernia of whatever description, always throw aside every sort of binder, which may constrict the abdominal muscles, and allow the infant the fullest possible measure of diaphragmatic movement. (Jour. Am. Med. Ass'n. Sept., 1891.)

The hernia of the aged—another extreme of life, unless in very exceptional cases should not be interfered with. At this epoch of one's existence, the blood vessels have undergone degenerative changes, the sac has become, so inextricably blended with the elements of the cord, that its isolation is often difficult and sometimes impossible. Strangulation in the aged is a rare event. I have never seen it in one over 65 years in either sex. There is scarcely anything except this latter condition, which will ever afford us, any justification for operation in this senile state.

Hernia in the male sex, being so common and will occupy us so frequently, that it would seem, that something might be said of sexual peculiarities, in their bearing on the treatment. The chief difficulties in the way, in the treatment of male hernia, are the laborious occupations of the majority of men, and the great trouble in effectually barring the portals of hernial escape; while yet preserving the spermatic cord, from immediate injury, or from the ultimate pressure of a contracting scar. Yet, notwithstanding these drawbacks, so much relief, and to so large a number has been given, and so many permanent and enduring cures have been affected, as to not only warrant a continuance of operation, but also stimulate us, to renewed efforts, in devising means, by which they may be shortened, simplified and rendered more and more effectual.

However, every case must be seperately studied, before we can always, come to a final conclusion; not only, as to the particular operation; but, the most appropriate to each case; nor should we make forecasts as to final results in every case.

Female Hernia.—Female hernia, as it is much more rare, than the opposite variety, we have been in the past, less frequently concerned with its management. Nevertheless as womens' herniæ are commonly more painful and liable to mortal strangulation, the safest and most effectual manner of relieving them should engage our most serious attention.

For anatomical reasons, they have, but seldom, inguinal hernia; for the reason that they have practically no inguinal canal; this rudimentary passage being always completely obliterated in the adult woman and never permitting of any extraneous substance to enter it except, in cases of congenital defect, in development.

Crural hernia is the phase with them which visceral protrusions so often take. As many of these herniæ are unmanageable to truss-support, and threaten strangulation, operative measures are not unfrequently invoked for treatment. Since laparotomy has become so common an operation, we are beginning to see a considerable number of cases of eventration, more or less of the abdominal viscera, which make their way through the weak or enclosed fascia propria, into the subcutaneous tissues, thereby constituting a sort of traumatic hernia, which I have designated laparotomy-hernia or rupture; for their affinity to laparotomies. When these are discovered and treated by appropriate pressure and support, in their early stages, much benefit may follow. But when they have attained a great volume, surgical intervention may be considered.

At the late meeting of the British Medical Association, Lawson Tait described a method of treating hernia, by making an abdominal incision and drawing the sac and viscera upward, then closing the ring from the inside with the aid of a suture. This he particularly advised to be always done when one did an operation on a woman for the removal of a tumor, taking advantage of the opportunity when the abdominal cavity is open, to extract the hernia and effect a cure. His views, in the Section on General Surgery, before which his essay was presented, met with but little support, though it was generally conceded that in these hernia-bearing women, who were to be laparotomized, the idea was a good one, in simple reducible herniæ.

Congenital Hernia.—I have grouped under this head every sort of hernia which is visible at birth. As a rule, on examining the scrotum after delivery, it will be found that boys have a scrotal development rather out of proportion, in volume, for their general development. We will always observe that the cremaster muscle is of considerable thickness and density, and that there often is a conical contour of the spermatic cord from the expansion of the fibres of the external oblique, at its external outlet, giving an impression to the touch, and the appearance to the eye, of a hernia. My own impression is, that in the vast majority of male infants born, the funicular process is not completely closed for varying periods after birth. In those where no impediments to the emunctories are found, and where the child is not taught to walk too early, it will usually close of itself during the first year; while on the contrary, under adverse circumstances, the opposite will obtain and a hernia may present. Hence, the mere fact that this funnelling is present, always more or less marked on one side than the other, is no reason that we should institute any sort of active treatment. Nature is competent to deal with this incomplete evolution. It is one of those manifestations which illustrate how often the infant reaches the world, in a sort of incomplete state of development, but in which, under a favorable environment, time will obliterate apparent defects.

There are now and then met with at birth, nevertheless, herniæ of considerable size, which are quite irreducible. Opinions are at variance as to the proper course to pursue with them. My own plan has been to recommend immediate operation, supplemented by the use of the truss. I have operated on the fifteenth day after birth, on a large scrotal hernia, and afterwards exhibited the baby before the Harlem Medical Association, the result being most excellent. And as many as a dozen I have treated by radical measures, under one year of age.

In a general way, however, unless there are some special and pressing indications, it is much better to follow the rule of Félizét, viz.: to employ first, palliative means, only, and not operate until children are over whooping-cough and measles.

Acquired Hernia, So-called?—Authors are accustomed to set down the causes of hernia, as predisposing and active.

My own experience has led me, to regard hernia of every description, as always, in *every instance*, as being attributable to so-called predisposing causes, solely and alone; to congenital ante-natal conditions; the active cause, being an incident only, and nothing more; bearing about the same relation to the infirmity, that a local injury does to a cancerous growth; hence the reason that I have intimated a doubt in the above designation.

It will be found on rigid scrutiny and a painstaking examination, in the vast majority of those so herniated, that they either had the disease in very early life, or that they had a sense of weakness at the seat of the hernia for a considerable time before it appeared. As the infantile hernia, is either undiscovered, or treated by a truss, and has disappeared before the child reaches the age of reason, he has no recollection of it, so that when it appears, only, after the lapse of several years, long after his parents have died, perhaps, he being ignorant of ever having had the infirmity formerly, he may in all sincerity deny its previous existence. Mr. Thomas Bryant in his excellent treatise on surgery; says, that the greater part of those early cases disappear, before the tenth year; but that later, when the abdominal muscles are put on a severe strain, through violent exercise or labor, they recur, in the great majority of cases. Inasmuch, as in all, which I operated upon, under one year of age, the sac was in every case, thick, tough and firmly adherent to neighboring tissues, it was evident that the *fascia-propria* had been extruded a considerable time before birth; probably contemporaneously with the descent of the testis. It is very probable, that in all those cases of cure of hernia in infants, the viscera are returned to the peritoneal cavity, the neck of the sac contracting only; hence in later life, on severe strain, its orifice is suddenly stretched and the viscera slide downward into a pouch, which awaits their advent.

It will be seen, then, that while tentative measures, serve a most useful purpose in early life, and so remedy very many hernial infirmities, that they never give any trouble, it is also evident that these herniæ constitute the ground work of the acquired, or consecutive variety later in life.

The treatment of the acquired variety of hernia, must be governed by circumstances; whether it is strangulation of very great volume, simple or complicated and other factors, which will be considered later on. It may be said, however, in a general way, that in this class, when a comfortable support can be tolerated; when there is no tendency to strangulation, in carceration or *hydrops Vaginalis* no operation is called for. Those acquired herniæ, so-called, are peculiar to women; as hernia with them of the congenital type is rarely seen; for it is usually with the advent of menstruation or child bearing that the infirmity makes its appearance.

Laparotomy Hernia.—It is said that from 25 to 30 per cent. of women laparotomized, suffer sooner or later, from hernia, through the line of incision. They constitute by all odds, the most unmanageable and melancholy phase of this infirmity, that we are ever called upon to deal with. They anatomically possess a close resemblance, with those large, massive exomphaceles occasionally met with in middle-aged, child-bearing women. Like them, their serous investment is of a purely adventitious description, as they have no true sac. As they make their way through the divided lips of the dissundered gap they, push the fascia propria aside and press on, sending prolongations into the inter-muscular spaces and under the integuments, which give rise to an irritation, that ends in a plastic inflammation. A webbing and netting of the capillary vessels follow, in consequence of which in time, the vascular structures of the abdominal walls and the chylopoietic viscera become intimately anastomosed. Muscle, tendon, ligament, aponeurosis, omentum, mesentery and intestine, become, in time, inextricably bound together. The portal through which this enormous mass escapes, very often remains of rather limited dimensions. One case on which I operated, wherein the hernial mass was larger than an adult head; yet the opening in the middle line, through which it escaped was no larger than would admit the finger. In this unfortunate class of cases, as time advances, one coil of the intestines will follow another, the mesentery so stretching as to permit the practical eventration of all the movable viscera. The economy adapts itself to this extraordinary derangement of the organs, so that, the processes of digestion are not seriously interfered with, except in very aggravated cases. Nevertheless, they practically cripple the patient and render her unfit for any occupation which requires activity and strength.

If seen, when they first appear and when they are of diminuttve volume,with few exceptions they should be promptly dealt with, by surgical operation. But, when they come under our observation, only when they have attained considerable size and have existed over many months an operation undertaken for their alleviation or cure, is attended with considerable danger to life. The necessary expansion of so large a quantity of intestine, the extensive hæmorrhage, are elements of danger, and what is the worst of all, is the calamitous effect on the respiration, caused by the sudden return to the abdominal cavity,of so large a mass. One only alternative, then, is mechanical support, such as is afforded by a bandage or a sort of sling. Certainly, in the event of strangulation, we must not hesitate, to immediately operate. But, our intervention here, has no parallel in technique, with that which we commonly resort to, in inguinal or crural hernia. Our aim should be, to simply relieve the restriction and nothing more; leaving the incarcerated viscera in their newly found abode, without making any effort whatever, to return them.

Hernia in those Suffering From Constitutional Disease.—The question often rises, when patients apply for treatment of painful, incoercible or dangerous hernia, whether, when they are suffering from organic disease,we are justified in advising radical measures; and when not, what alternative can we offer? It is well known, that many constitutional maladies often pursue a very chronic course and that not a few of them, pronounced incurable get well, when properly treated. This is notoriously the case, with the pulmonary, renal and hepatic disorders. However, as a matter of justice to our patient, unless his case is one of special urgency, tentative measures only, should be enjoined. It is a curious fact, that in reviewing the literature of hernia and recalling my own limited experience, there appear few records of strangulated hernia,in those suffering from serious chronic disease. Yet, there are, no doubt, occasionally cases in the unsound; male and female, in which an operation should not be refused. Heretofore, in renal, cardiac or pulmonary diseases, we can clearly understand why respiratory anæsthetics should be eschewed; and hence surgical measures contra-indicated. But, since the discovery of the valuable analgesic action of cocaine analegesia, this objection does not obtain. Many times have I demonstrated this, in male and female hernia; strangulated,incarcerated and reducible; with a successful issue in most cases. A hernial operation of convenience, in a delicate, sickly child or adult should never be entertained.

Regional Division of Hernia. Complete Inguinal Hernia.—As its name implies, this hernia indicates complete clearance of the two rings and the entire canal; hence we can appreciate the fact, that the cure entails its complete return, back, through the entire path which it traversed. Now, if this sort of protrusion were a sudden and abrupt event, analogous to a dislocation at a joint there would seem no reason, why it should not be treated on the same precise principles; for a hernia is always essentially a dislocation. If the capsule, ligament, tendon or muscle is lacerated or injured in a dislocated joint, after the displaced bone is restored, we place it in the best, possible position for its complete practical restoration.

In an acquired,complete inguinal hernia of the reducible type, we seek a cure, by the return, entire of the wandering structures. But, we have impediments, at times, which make their return, difficult and their permanent sojourn, in their normal abode impossible. The sac has acquired adhesions. We empty it but leave the receptacle, to invite hernial return. True, we may secure a sealing of its lumen by adhesive inflammation. The rings are abnormally wide. There is an undue lengthening out of the mesenteric ligaments and there may be a want of proportion in the capacity of the abdomen and its contents; as we see, in those cases, in which, when,we crowd back, a hernia, with a truss on one side, a fresh protrusion appears on the other. This is the phase of the infirmity, which is more managable to truss-pressure, than any other. It is only when a proper truss cannot be secured; when the hernia has attained a great size or threatens strangulation, that operations are called for here. Complicating factors, must influence our course though, as in other cases.

Incomplete, Inguinal Hernia.—Incomplete hernia or bubonocele, is less frequently seen than the complete.

Anatomically, it consists in the protrusion being arrested in its passage through the inguinal canal; or having slipped through the interior aperture, fails to lodge in the scrotal pouch. In many varieties of it, when one's occupation is not of a very laborious description, and it gives rise to no inconvenience, it should be left severely alone. It having become impacted, it so effectually blocks the passage, that nothing can pass it. Those bubonoceles, however, may contain within them, an undescended testicle or a neoplasm; and they, through constant pressure on the spermatic cord, may cause its atrophy; or they become strangulated at the internal ring. With the greater part of them, there is a tendency to increase in bulk, if no restraining measures are employed.

They are commonly borne without serious distraint, by the use of a supporting bandage. Though there are so many sequalæ which they give rise to, in several cases, that operative measures may be occasionally considered.

Compression of the vascular structures of the cord, in time, lead to diminution in sexual power, spermatocele, hydrocele or varicocele.

Not long ago, I was consulted by a veterinary surgeon who had a small, incarcerated bubonocele, over which, he wore a truss. He was a hearty, vigorous man, of forty years and had a wife of an ardent temperament; whose demands he had not been able to satisfactorily supply, for some time, before he consulted me. He came to me believing, that I would do an operation; for, his observations on the lower animals, led him to believe, that the hernia was at the bottom of his sexual impotence.

On examination, while I could discover no positive atrophy of the testis, yet it was of a soft, flabby consistance, on the side the truss was worn; besides, its fellow was rather undersized, for a man of his stature. The veins of the spermatic cord although not decidedly varicose, were nevertheless, enlarged and thickened. On making a very thorough examination of the hernia, I concluded that the small nodule which occupied the inguinal canal was not the bowel; and, it being firmly fixed, by adhesions making no impulse against the finger on coughing. I decided to recommend him to discontinue the truss and wear nothing whatever, except a hank of woolen yarn; and this only on any day when he had to perform laborious 'duties. My advice was followed with the most gratifying results in every particular. The hernia has not increased in size and the sexual powers are all that could be desired.

There are cases of this variety, of hernia, however, in which, the most astute must consider carefully, before advice is given. They must not only be very carefully examined, but thoroughly studied as well; for not only is our patient's future comfort and happiness at stake, but even his life as well.

The following case illustrates this fact.

A man of forty-two, came under my care at the Harlem hospital four years ago; for the treatment of a strangulated, incomplete inguinal hernia. His history was that since a boy of ten, he had a small, fullness in the right groin; for which, for many years, he had worn a truss. But, for more than ten years previously, to entering the hospital he had thrown the truss aside; no trouble coming from it, until now. He was married, and the father of five children.

His symptoms being urgent an operation had to be immediately performed for strangulation. As the tissues were divided and the sac opened, there, side by side, with a strangulated intestine, lay an undeveloped testis. This man was a monorchid. He never properly rallied and died two hours after operation. As his scrotum was much distended, it gave the appearance of symmetry. Had the practitioners who had first seen him recognized the true pathology of his condition, instead of making prolonged and futile taxis; or had they advised operation twenty years earlier, he undoubtedly would have completely recovered from operation and have been cured of his hernia as well.

Hence, in these cases, before we pronounce an opinion or specify the line of treatment, to be followed, we should, in every instance, be assured of the presence or absence of the testes. If both testes have descended, then we may, in all cases, with few exceptions depend on tentative measures. But every time, when we discover a bubonocele of any considerable size and that the testicle is absent, on that side, the organ should be cut for, and forthwith removed; at the same time executing the technique for radical cure. It may be well, to not forget, that operations for bubonocele are not so satisfactory, in their permanent result, as are many other herniæ. The pressure of a large mass against the abdominal wall, over many years, causes a thinning and wasting of the aponeurotic structures, which, when operated on, possess a low vitality; so that in many of those, we operate only when we must, for strangulation, for example; or, to put the hernia in a more supportable position. I am not certain, but in many of those cases with ectopic testis, an incision for its removal without any unnecessary mutilation, would, in the end, accomplish as much, durable good, and less danger to life; than an operation of a more tedious and dangerous character.

Direct Inguinal Hernia.—The diagnosis of direct inguinal hernia is a physical impossibility. It is true that by the aid of the scalpel and a delicate dissection, it may be made out; but, not by any other means. I have never met with but one case, which, I was quite assured, was a hernia of this type, at the time of operation. My conviction is, that it is a very rare pathological entity. Indeed, in those old inguinal herniæ of considerable volume, in which the inguinal canal becomes quite obliterated and the hernial vent, is simply a large hole, in the aponeurotic wall, it doesn't seem, by any means clear to me, how even on dissection, the differential diagnosis of the direct, from the indirect, is possible. Indeed, I would deny its possibility. Anatomists would tell us, that the one, should be readily recognized, from the other, by its coverings. But, we are not dealing with normal structures. They have undergone such pathological changes that the investing layers have become greatly changed in their histological elements; atrophied, hypertrophied; or fused together by adhesive inflammation.

Happily, it is of little consequence in treatment, except in operation, when we are told, that in the direct variety, that as the mass comes down to the inner side of the epigastric artery, the edge of the scalpel must be carried in a certain direction, if we would avoid a dangerous hæmorrhage. Those anatomical refinements are of little consequence, when we come down, to the act of operation.

The direct, complete inguinal hernia, when of long standing; when the outer walls of its sac have become firmly bound down to the cord, when the testis and perchance the contents of the sac have become adherent to its inner serous surface, and a large breach is made through the abdominal wall, we must always consider, it as an infirmity of an inoperable description; which can never justify surgical intervention, except, in the event of a strangulation. If the interpretation of this hernia is correct and it has been properly defined; then, even though no adhesions were present, the excision of its dense, tendinous sac; leaves a hiatus in the abdominal wall, liable to lead to unfortunate consequences ultimately.

Inguinal Hernia, in the Female.—It is said that inguinal hernia in the female, is about as rare, as femoral, is in the male. The morbid anatomy of female, inguinal hernia, is comparatively simple. The presence of the vascular supply of the testicle, coursing through the inguinal canal in the male, gives rise to a multiplicity of painful complications; and their absence, in the canal of Nuck, in the female renders this form of hernia with them, seldom a source of much inconvenience, except in the marriage state.

At the crest of the pubic brim, the parts being so deeply covered with fat and hair, a hernia unless of considerable volume, or morbidly sensative, is apt to be overlooked and the patient may go through life, without a suspicion of its existence.

Inguinal hernia then, in the female is devoid generally, of those attributes which cause so many painful concomitants; as they are commonly small in volume; and when reducible are easily coercible. However a large number of them are painful, and quite rebellious to treatment by the truss. They may be reduced and pressed backward by this instrument, but they cause so much uneasiness and misery that the patient often feels much more comfortable without any sort of mechanical aid and throws the apparatus aside. This is explained, by the fact, that in female inguinal hernia, any single one in part, or complete, of the genital organs may occupy the sac and constitute the protrusion. If one of the reproductive organs has not come down, directly; the omentum in its descent, having formed adhesions with some one or more of them, or their appendages causes all these symptoms, which we might any time look for in ovarian or uterine displacements. Such was Dr. Barber's case, which had baffled medical attendants. Not being able to find the uterus, on vaginal examination and discovering that his patient had a large, unmanageable inguinal hernia, he decided to operate, when he found the entire uterus, wholly outside the abdominal cavity; bound down by old adhesions to its peritoneal investments. The doctor then proceeded to secure a radical cure, by resecting the uterus and closing in the chasm. (*Am. Gyn. Jour.*, Dec., 1891.) Dr. Perry Schoonmaker exhibited before the Harlem Medical Society of New York, in March, 1892, a year old female infant who having a large unmanageable inguinal hernia, he cut down, on it and found it to consist of a prolapsed ovary. The doctor practiced the most praiseworthy conservatism. Freeing it from its attachments, he returned it to the peritoneal cavity and effected a permanent cure of the infant. For other reasons, besides those enumerated, in the vast majority of inguinal hernia in females; as soon as the hernia is discovered it should be treated by prompt, surgical measures. Strangulation in the female is terribly mortal. Very much more so than in men. A curative operation prevents the possibility of it occurrence.

Each successive confinement is almost certain, to aggravate the infirmity and increase its volume. The canal-of-Nuck, through which the viscera escape in women, can be, without endangering any organ, solidly, hermetically sealed up and very possible prospect of permanent cure offered. To the young woman contemplating matrimony, in order to remove the blemish and infirmity of hernia, an operation should in every instance be recommended. Applicants are admitted into the cavalry arm of the British service after they have been cured, by surgical operation of their herniæ; who had been previously rejected. As a prothetic measure then, in addition to others, the simple, safe and efficient operation of kelotomy, may, in every case of inguinal hernia, in the female be taken advantage of; as offering in the greater part of them, everything that can be expected. The unfortunate young woman, heretofore aware of her infirmity, is conscious of her physical inferiority, bewails her misfortune and dreads the approach of the time, when she can no longer conceal its existence and she is open to the charge, of having been physically unfitted for the married state. Surgical intervention in her case, instituted under proper environment, is devoid of peril and the operator who carries his incision well over the lateral slope of the *mons-veneris*, being cautious to limit its extent, will so completely obliterate every trace of the scar; which, will be effaced by the re-growth of the pubic hair. The earlier in life the operation is performed the more complete, will be the assimilation of the cicatricial tissue and the total disappearance of the former deformity.

Crural Hernia, in the Female and Male.—Femoral hernia in the adult female is the most common of all varieties. For many anatomical and physiological reasons, operations for its effacement are very often unsatisfactory and are frequently followed, by relapse; so that in only exceptional cases can they be regarded, as appropriate adjuvants in the way of cure. Hence, it is in only the minority of them, that active surgical interference is demanded. But, these are sufficiently numerous to always warrant a careful study of them, before we attempt their cure or relief by any therapeutic resort, which entails the loss of blood. The great obstacles in the way, in treating female, crural hernia are, the presence of the two great blood trunks. of the lower extremity, which pass immediately through, or are in close contact with the common hernial sheath, the *fascia propria;* and, with the married female, the recurring strain of parturition; the varying volume of vena-saphena; and, puerperal phlebitis in the veins of the lower extremity.

Many times, in operating on femoral hernia, particularly in the strangulated variety, have I met with such close and intimate fusion of the walls of the vein with the sac, that it required a very delicate and tedious dissection to separate one from the other. On one occasion, while making such a dissection, in a femoral-epiplocele, I accidentally, opened into the femoral vein. Moderate pressure, however, easily controlled it and a permanent cure resulted. When, after considerable time, the saphenous opening in the fascia-lata, has attained to increased dimensions, the femoral curve is practically effaced, and nothing remains, but a large ring. In cases of this type, the permanent closure of this large portal, in such a manner, as will prevent the viscera again slipping down, under the crural arcade, during the strain of active labor. is impossible. In any event, extreme caution must be always observed here, while endeavoring to close the vent, not to excite so much inflammatory reaction as will cause such pressure on the vein as will in any way interfere with the free return of the blood, from the lower extremity. The great difficulty in accomplishing this, constitutes one of the almost insurmountable impediments to the more general adoption of operations for femoral hernia.

Which then, are the cases of femoral hernia, that may render operations on them, imperative? They are in epitome, those of strangulatior the incoercible and the painfully incarcerated.

In my experience, operations for strangulated, femoral herniæ in women are by far, less fatal, than for inguinal, in the same sex.

By incoercible, is meant those herniæ, in which a truss cannot retain the hernia with comfort; and, there is a tendency to symptoms of impending strangulation. Here, clearly, where life is imperilled, or made wretchedly miserable, there is scarcely any middle course; and, if there are no pronounced contra-indications surgical relief should be immediately resorted to; for, even if permanent cure is not secured, danger of death from strangulation is forever obviated; and besides the protrusion is so placed, as to be comfortably supported, by a truss.

We should be guided by the same general principles, in the treatment of femoral hernia in the male, as in the female; except, that owing to the wide physiological difference in the pelvic functions of the two sexes, hernial operations, for this phase of the infirmity offer much greater prospects for successful results in males. Nevertheless, when a femoral hernia occurs on the same side as extensive varicosity of the saphenous vein and its tributaries, we should hesitate, and weigh well the consequences, before we resort to any procedure which may, in any way, embarrass the free flow of the veinous current through the great trunks in the ham.

Umbilical Hernia; Exomphacele, Median-Ventral Hernia.—I have seldom seen umbilical herniæ in the adult male; although I have met with a considerable number in the matured, child-bearing woman.

In approaching the consideration of the treatment most appropriate, in this class, we must constantly bear in mind the morbid anatomy and clinical history of umbilical hernia; its causes, and the conditions which favor or retard its cure. In those naval protrusions so commonly seen in early infancy, which give rise to no serious symptoms and which disappear of themselves, any sort of cutting, to efface them, is little short of a downright mutilation. Impediments to the free passage of the urine, whooping cough or measles may retard their disappearance, but, as age advances and these incidents are passed, the erratic visceras return and the orifice contracts, so that, as a rule, from the tenth to the twentieth years, we will very seldom see this genus of hernia. After they once disappear in the boy, it is very rare that they return. With the female, on the contrary, they often, again, make their appearance, not uncommonly, giving rise to embarrassing symptoms, and often, even menacing life itself. We have seen, that these herniæ spontaneously disappear in infancy; but, in adult life, they occupy a fixed position, in most women, in whom their tendency is rather, to increase than diminish in volume. Certainly, dangerous eventualities may occur, depending in a large measure on recurrent pregnancies and the occupations or position in life, of the afflicted. This being the case, one would on superficial examination of the subject, assume that the return of the wandering viscera, with the simple closure of the outlet, should be the proper course of treatment in every case. It is as a rule, however, unusual, that they give rise to any serious inconvenience; hence the patient would be quite ignorant of their appearance, if she did not see them. With these, the simpler, the treatment, the better; and, it should be directed, as much to the mind, as to the hernia. The assurance, that the slight fullness will probably, never give any trouble; the application of a light, soft belt or binder are ample; with a caution, to avoid any sort of heavy straining; are all that is necessary with this minor class.

The most serious cases of so-called umbilical hernia, however, are rather ventral, than umbilical; *i. e.*, they make their escape from the abdominal cavity, rather above, below, or on one side of the naval aperture, than through it; and, instead of pushing an investment of the peritoneum before them, they rather, by pressure or otherwise, rend this membrane and pass through; hence, are genuine properly so-called; and, in consequence have no true sac, but rather an adventitious investment of areolar tissue.

In order to have an umbilical hernia proper, we must always have the elements of the urachus and round-ligament of the liver, outside the abdominal wall; a very few cases of which are recorded in surgical literature.

Herniæ of this description may attain an enormous size. I saw one lately in a young widow of 35 years, which contained the greater part of the floating viscera; and, which hung down over the pubis. It in no way interferred with her general health; and produced no visible deformity under her clothing. It was supported by a sort of sling belt. Regardless of their size or situation, nevertheless, these herniæ when free from severe pain, or prospect of strangulation, they belong to the inoperable class. The proximity of their situation to the great, central ganglia of the sympathetic, the solar plexus, the usual abundant and intimate adhesions of a heterogeneous character, the muscle sheaths, aponeurosis, mesentary, omentum and intestine, always makes this separation, isolation and return of the extended viscera, a very bloody, difficult and always dangerous procedure. Besides, what is worse than all, the calamatous consequences, liable to follow, the sudden increased intra-abdominal pressure, occasioned by the immediate return, of a mass so long lodged externally, that it practically becomes a foreign body. It has long been observed that the sudden evacuation of a serous cavity is not a harmless measure; and, *per contra*, the abrupt distension of any of them, is always a menace to life. So that, should we meditate a radical operation, we should always commence, by endeavoring to effect the gradual return of the viscera by taxis, and then, when it is evident that tolerance has been attained, we may essay; a plastic operation to close the vent. But, as the greater part of them are incarcerated, we are not able to avail ourselves, of this expedient.

It is only then, in those ventral herniæ, in which the patient is menaced by strangulation, or that they make life unbearable, that a capital operation for their cure, is at all, a permissible expedient. Exigencies will, though, arise, when the surgeon must be prepared to act; and, even in these unpropitious cases, be prepared to promptly interfere and save life in strangulation, in the umbilical region; or in the less serious, do so much as will give comfort and remove all apprehension of future danger, from strangulation. When these herniæ are attended with periodical spells of colicy pains, are incarcerated and painful, the practitioner must be on his guard, for symptoms of strangulation. I saw a case of this type of hernia, during the past year, in which, through failing to recognize it, until too late, a life was lost. The patient, the wife of a physician, had the hernia 30 years. When I saw her in consultation and recognized her real condition, she was having stercoraceous vomiting and was in a collapsed condition, presenting such a hopeless aspect that I deemed an operation inexpedient. Last October (1891) a woman was sent to me suffering from periodical fits of strangulation in an umbilical hernia. Although her hernia was as large as the fist and there was free hæmorrhage; she made a good recovery, after operation and so far there is no sign of of relapse.

Division of Herniæ on a basis of their morbid Anatomy and Pathology. Simple Hernia in General. In Youth.—Under this head, I have grouped all herniæ found in such a position, of such a size and situation, as to give rise to no inconvenience; immediate, or remote; and, which, are devoid of any serious complicating factors.

The human offspring, at the time of birth, has but partly effected its evolution; imperfection physically, at this epoch, of life is the rule. The position which the symmetrical organs occupy, bears but little or no relation to what they will later in life, at the mature stage. Want of coördination and symmetry is now observable on close inspection and many conditions are now observable, which might at first, be regarded as malformations, are but slight deviations, which it was not allowed Nature to complete, before the child was borne into the world; but which time will remedy, provided the offspring survive. These defects, one will most readily observe, in the arches of the jaws, the outlines of the spine, the position of the limbs, and the varying relative size and contour of the cranial and facial appendages, particularly the nose and its septum. With these must be added those simple herniæ, in which, in the absence of coughing or unusual straining, with the infant in the dorsal decubitus the greater part of the time; in the first year, they commonly disappear, as the formative processes advance.

Strangulated Hernia.—Strangulated herniæ, until very modern times, were always, first treated by the tentative means, before radical measures were resorted to. In our own times, there are not a few cases, in which we must follow the same course; but one of the great difficulties, in the way, is, not being able to always say with certainty, what the immediate results of an operation will be.

In the greater number of strangulations we will have such pathological conditions as generally call for immediate relief. They are, pain, inflammation and obstruction of the bowel. In some, we may have the bowel constricted for days and then reduced without serious detriment. While there are other cases presenting mortal symptoms, after a few hours. If we could always promise recovery from operation and a permanent cure of the hernia, we should in every case, at once, cut down on the hernia. But we can promise neither. I have seen many patients die from shock, after operation for strangulated hernia. Certainly, when we do cut them, we should always simultaneously, do the radical operation, for cure.

Those patients so afflicted, accordingly, will be treated by palliative and direct surgical measures. In the old, infirm, we should endeavor to relieve by taxis first. Taxis has its limitations; and, when not skilfully applied, does more harm than good. Hence, when one has used moderate force and failed, unless the patient stubbornly refuses surgical interference, he should desist, and advise liberation of the construction with the knife. I am not sure, but in a large number of cases of reducible hernia, which become strangulated, the patient's prospects would be vastly improved, if topical application alone, were depended on, with complete rest and sufficient morphine to reduce pain, the hernia left to the patient himself to deal with, rather, than to the employment violent and misdirected taxis. It is commonly the experience of hospital surgeons, to meet with cases, in which, the outside practitioner, having exerted himself, in vain, in oft-repeated efforts at taxis and finding symptoms of collapse setting in, sends the case in for operation, at the eleventh hour. Two such cases have come into my service, which didn't survive an hour after they were admitted; one an old man and another, a young woman.

As the operation for strangulation is not a difficult one, and the mortality is very slight, when performed early, we are justified, in almost invariably, advising it, when moderate taxis fails. I am acquainted with no case of restrangulation in any one who has been operated on previously. On the other hand, a case temporarily relieved by taxis is liable any day to again, place the patient in the same peril. Further, although we certainly are not in a position, to guarantee, in every case a permanent cure, when the radical operation is performed, yet, we may assure our patient with every confidence, that the chances are against relapse of the hernia. I can find no statistics on this particular question of recurrent hernia after operation for strangulation; but, in twelve or thirteen operations for the strangulated condition, in my own practice, hospital and private, within the past three years, when I have conjoined to the relief, radical measures for cure, not a single one, to my knowledge has relapsed. and in every instance, the double purpose was accomplished of relieving the strangulation and curing the patient of his painful infirmity. Since the introduction of cocaine analgesia, into surgery when employed by myself in those cases of terrible depression of the vital powers, there have been no deaths; while with the same class, when pulmonary anæsthesia was employed, formerly, the mortality had been considerable; many dying before the effects of the anæsthesia had quite passed away. With those patients who have a horror of being rendered unconscious and are restrained from operation through this fear, no doubt very many would cheerfully submit, if they thought, they might be effectually relieved, in the full possession of their senses, without the infliction of pain. A full knowledge of the powers of this invaluable drug, in hernial operations will no doubt, tend to the much greater frequency of prompt and efficient surgical intervention, in a class, heretofore, reluctant to avail themselves of the great value of the operation for radical cure.

Incarcerated Hernia (of every Type).—The morbid anatomy of incarcerated hernia furnishes us, with an excellent illustration, of the very best work which unaided Nature can perform, in the way of protecting a condition, against accident which an imperfection, in her own processes has caused. And, when the term incarcerated hernia is employed here, it is intended to portray only, that type of hernia, which is held *en masse*, outside the portal, through which it has passed. For, there is scarcely no hernia, (if we except those, which make their appearance and are strangulated simultaneously) that have a peritoneal investment, but are in part incarcerated. We may designate them reducible; but, they essentially are not. *In all old hernia, and, the congenital variety, as well, the sac is invariably bound down by adhesions, is irreducible and hence, is incarcerated.*

An incarcerated hernia maintains an independent existence. It forms new alliances and draws its sustenance from extraneous sources for the main part. By plastic inflammation, it becomes on its surface, and in its center, practically independent of the general, visceral, vascular supply, and is supported by those vessels, which course over its outer aspect, in the periphery, or the areolar tissues.

They are practically of two varieties only; viz.: those which are small, solid and devoid of impulse on coughing. In many particulars this group is harmless, in themselves. They need no truss to control them; for so large an amount of dense, fibrous tissue has been thrown out about them, as to firmly hold them in position. They cannot become strangulated; because there is nothing to strangle. It is then, only, by the enlargement of a passage that their presence maintains and permits a loop of intestine to engage in it; and that they can ever occasion danger. My impression is, that with the great preponderance of them, they are wholly congenital; or else are caused by the malapplication of a truss, which, by its irregular, or undue pressure excites inflammation. When they are of diminutive volume, there can scarcely be a question, but they are not infrequently obliterated by absorption; when so little residue of them remains, that in the inguinal variety, in the male, at any rate, they cannot be isolated from the elements of the spermatic cord. The other variety, is the most numerous and troublesome. They are of considerable size and include intestine as well as hypertrophied omentum. The pouches which contain them, often attain a great volume; especially the umbilical and scrotal types of them. They constitute one of the most lamentable phases of hernia. While the larger seldom immediately endanger life; yet, as they cannot always be relieved, or effaced by art, the victims of them are doomed to pass their days in constant discomfort, the hideous deformity, which cannot be concealed, remaining, to further embitter their existence by inviting the curious gaze of those, unaccustomed to see such deformities.

With this latter type, of incarcerated hernia, nothing can be promised by operation, except in cases of strangulation, where the surgeon must limit his intervention to relieving the constricted neck, unless, the presence of gangrene in the eventrated mass is suspected.

With those, first described in this class of hernia, unless this innocent extension interferes with the nutrition of an organ, or contiguous parts; as by pressure, nothing whatever should be done. I am quite confident that with them, the ordinary truss is only a source of discomfort and nothing more. But, when, as in inguinal hernia, we see the testis undergoing atrophy in consequence of the pressure they cause, or we suspect a twist in the spermatic cord and want to release it, the inguinal canal being opened, we may take advantage of this opportunity to cure the hernia. With these exceptions these innocuous incarcerations should be left alone.

It is only with the incarcerated of intermediate size, into the composition of which, the gut enters, that the question of operation rises and it is in these, that the most brilliant results are observed after surgical intervention. Operations on this variety of strangulated hernia, are prophylactic, palliative and radical. They are principally prophylactic, when we resort to them, to prevent an impending strangulation, or to obviate the tendency, to their enormous increase in volume; as in umbilical or ventral hernia. They are palliative only, when we aim to simply return the bowel and place the hernia; so that a light truss may safely control it.

They are operative, when the hernia is of the congenital type, anatomically; when the testis and abdominal viscera, lie in the same, common envelope, and all, have been welded together, by adhesions; when the abdominal contents can be restored; when a sac is present it can be isolated from the cord and excised; and, when the inguinal outlet can be completely occluded. Irreducible crural and umbilical hernia will be managed on essentially the same principles, as the inguinal type.

It may, indeed, be said, that if those incarcerated herniæ, which manifest a tendency to rapid increase, are not treated promptly by operation, the time soon passes when interference, will be attended with success, or even permissible.

Enterocele and Epiplocele.—A knowledge of the anatomical components of a hernia will go a considerable way, in enabling us, to form an estimate of probable results of operation, and besides a correct interpretation of their condition, will suggest the best line of treatment.

We know, for instance, that a mere spasmodic grip on the neck of a mass of omental fat, an epiplocele can do no harm; but, on the contrary, by reducing the blood supply, it may effect such atrophic and degenerative changes as will in time, practically efface the hernial tumor. We know too, that when we cut for the cure of a hernia, and it is an epiplocele, by excising it high up, a relapse is impossible; for the reason, that the cause of the hernia, has for all time, been removed. With a strangulated intestine, the local and general symptoms are of a startling character and, if unrelieved, are inevitably fatal, in a very short time.

No operation has been or ever can be devised, which will always, or even in a small minority of cases effect a radical cure of an enterocele when of any moderate volume; for its cause yet remains. Its own excessive length or dimensions have not been reduced, nor, has the mesenteric ligament been shortened by operation. When the mass is of a mixed character, partly omental and partly enteric, however, we may secure a permanent cure by excision of the sac.

This difference is important to always bear in mind, when we are undecided, as to which course to advise, and when the patient demands an assurance of probable results. An operation on an epiplocele then, is always a simple, safe and curative measure; while on the bowel, it is not so free from danger and is always of dubious value, as a measure of permanent relief from hernia.

Having had no experience with unusual and rare descriptions of herniæ, as perineal, obturator or lumbar; and, besides, believing that views on the most appropriate management of them, based only, on knowledge, gathered from the text-books and theoretical notions, would serve no useful purpose, I have purposely omitted their discussion. Nor, have I entered into a detailed description of the complicating factors and multiplicity of abnormal deviations of an anatomical type, which are commonly met with in the hernial diseases, here considered, feeling, that while endeavoring to condense as much as possible, rather, too much space, has been occupied. And further, for the reason that as my opportunities for observations continue and time will permit, the description of these, will later, engage my attention.

CONCLUSIONS.

Although during the past fifteen years, very much has been written on hernial operations; much in America, but more in Europe; so far as can be learned in the current, home and foreign medical literature, no one has made an attempt in a methodical manner, in any brochure or treatise yet published, to systematically describe and classify those herniæ which are operable and those which are not. For the purpose, of at least, in part, filling in that gap this essay is offered.

In epitomizing the subject and considering the question of treatment of hernia in a general way, it may be said, with definite certainty. * * * *

1. That inasmuch as no operative scheme yet devised, or even can be; will always effectually remove the causes of every species of hernia; in consequence of this, a permanent cure, is out of the question, in certain cases.
2. The radical cure of hernia may be regarded as one of the most satisfactory operations in surgery. The fact that the disease often relapses, constitutes no valid objection against surgical intervention; for this is commonly the case in the major part of operations performed on the human body.
3. A radical operation for a non-strangulated hernia, which gives no serious inconvenience is not a justifiable procedure and should not be encouraged, unless there are pressing reasons for it, as the presence of a neoplastic growth in it; a prolapsed ovary or other viscus.
4. Hernial operations should not be performed in extremes of age. In very early life, there is seldom pressing necessity for them. In very advanced life, the risk, immediate or remote, to life or health, involved by operation more than compensate in the prospective benefit.
5. Unless, there are especially contra-indicating factors in given cases, inguinal hernia in women should be always treated by a radical operation, which, with them, is so often attended by a permanent cure.
6. As a rule, all operations on reducible, or incarcerated herniæ are radically curative, though the *disease commonly relapses*; nevertheless, the immediate danger of strangulation has been removed and the hernia has been placed in a position, to be more comfortably borne by a truss.
7. Every operation for strangulated, inguinal hernia, should always include, such additional steps, as will effect, thereafter a complete obliteration of the inguinal canal but permit the passage of the spermatic cord and, remove the chances of a hernia again occurring.
8. Very large, old herniæ, in any of the abdominal regions are not operable; except, in the event of strangulation; as their return, is attended, frequently, with mental consequences.

IS AMPUTATION EVER INDICATED IN COXITIS?

Read in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association. held at Detroit, Mich., June 8, 1892.

BY HERMAN MYNTER, M.D.,
PROFESSOR OPERATIVE AND CLINICAL SURGERY, NIAGARA UNIVERSITY, BUFFALO, NEW YORK.

I have no intention of describing the methods and dangers of amputation in the hip-joint, but simply to inquire into its indications in coxitis. That it has often been done we may learn from the table in the International Encyclopedia of Surgery. 276 had the operation done on account of disease, 65 of which, at least, had coxitis and many of which had been previously resected. Ashhurst gives a table of 34 cases of primary and 31 cases of secondary amputations for coxitis (probably the same 65 cases mentioned) with a mortality of 31 per cent. He states that the mortality is almost exclusively due to constitutional conditions and very little dependent upon the management of the wound.

Primary amputation for coxitis will, of course, be abandoned as surgeons, little by little, learn the indications for excision and also, that done at the proper time, this operation is not dangerous and the results quite excellent. It is, therefore, only with secondary or consecutive amputation that we have to do, the indication for which, according to Ashhurst, occurs, when after excision the discharge increases and it is evident that caries has recurred and is too extensive for spontaneous recovery, re-excision or, when with the same conditions, the patient's general health begins to fail.

We may properly ask, what the cause is for this increased discharge and the recurrence of caries? The increased discharge depends probably in all cases on improper antiseptic precautions and on the imperfect extirpation of the tuberculous capsule, pieces of which have been left behind, and it may be prevented by exercising due care in this regard during the operation.

The recurrence of the caries is probably less a recurrence than a continuation of the original trouble, particularly in the form of a chronic osteomyelitis in the shaft of the femur, and it is about the treatment of this particular affection that I wish to offer a suggestion in this short paper.

In some of my earliest resections for neglected cases of coxitis I have occasionally found a chronic osteomyelitis and osteitis extending all the way down the shaft of the femur to the lower epiphysis. The periosteum was found thickened, swollen and so easily loosened from the congested and osteoporotic bone, that the whole shaft could be forced out of the wound, leaving the periosteum intact like the finger of a glove. Necessarily we would in such a case find continued suppuration and recurrence or rather continuation of the carious process, unless we removed the whole diseased shaft, in which case, if we succeeded in healing the wound, we would get a useless flail-joint.

It is obvious that to make a resection and leave the diseased bone behind is useless, and to remove the whole diseased shaft produces a useless limb. Amputation has so far been the only resource and the various text-books on surgery recommend this proceeding under the circumstances mentioned.

And yet, by a very simple, easy and reasonable operation we are able to overcome this complication, if I can judge from a couple of cases lately operated.

Case 1.—Augusta P., aged 11, entered the Sisters' of Charity Hospital on February 12, 1892, with the following history: When six years of age she fell down stairs injuring left hip. She has since complained of slight lameness until last May (1891), when it increased, accompanied with fever, pain in the knee, emaciation, etc. Left leg abducted, flexed and rotated outwards; marked lordosis and crepitus in joint. A large cold abscess over anterior part of femur.

The abscess was opened by incision, four inches long, the tuberculous membrane removed with sharp spoon, the wound closed with sutures. It healed by first intention and gave no further trouble. The joint was thereafter resected by posterior incision, the bone being cut through above trochanter minor. The head was found loose in the joint, the synovial membrane of which was tuberculous and was removed. The whole neck and trochanter was in a state of chronic osteitis, no particular primary lesion being found. A chronic osteo-myelitis was found extending down through the shaft to the lower epiphysis, the cavity being found filled with tuberculous masses, softened bone and fluid fat. The periosteum was swollen, thickened and could with ease be detached from the dark red, congested bone. I decided to treat this complication in the same way as I would treat acute osteomyelitis and therefore removed the whole marrow and all the softened bone with a long sharp spoon, made thereafter with a chisel a counter opening into the cavity of the femur above the external condyle near the epiphyseal line, brought a strong piece of silk thread through by aid of a long probe, and after a thorough disinfection of the cavity with corrosive sublimate introduced by aid of the silk thread a long mesh of the iodoform gauze through the whole femoral canal and out through the resection wound. The acetabulum was thereafter plugged with iodoform gauze, the wound partly sutured and antiseptic dressing and a Volkmann's sliding splint with 5 pounds weight applied. The wounds were dressed every six days under narcosis for four weeks, a new mesh of iodoform gauze being introduced each time by being attached to the old one before it was removed. As the wound then looked perfectly healthy, the mesh was omitted and the wound then closed rapidly. The extension was discontinued on April 15, a plaster cast applied on May 4, and on May 10 she left the hospital on crutches in excellent health, having gained 12 pounds in weight. The shortening was one inch, the joint firm and freely movable, all wounds healed. She will not, of course, for three or six months be allowed to use the limb.

Case 2.—Thomas M., aged 13, entered the Sisters' Hospital on March 17, 1892, with the following history: He began to complain in April, 1890, of pain in the left knee, limping, had fever, starting pains at night and emaciated rapidly.

A plaster cast was applied by an orthopedic surgeon and allowed to remain on for three months, the child meanwhile walking on crutches. An abscess was then found on anterior part of femur and lanced, but did not heal. He continued under same treatment till July, 1891, and had since then been wholly neglected.

On entering he was extremely emaciated and anæmic, walked with two crutches. Left limb adducted and flexed, apparent shortening with marked lordosis. A sinus was seen in Scarpa's triangle discharging curdy pus. Under narcosis the sinus was enlarged and was found leading to the joint, which was then resected by posterior incision, the bone being severed above trochanter minor. The joint was found in a state of chronic arthrotitis, but not tuberculous, the cartileges being more or less transformed into a fibrous tissue forming strong adhesions and making the removal of the head quite difficult. The neck and trochanter were found in a state of chronic osteitis with formation of a number of cavities containing tuberculous material and bone-detritus.

The same condition was found extending through the shaft of the femur down to the lower epiphysis. The marrow was removed with sharp spoon, a counter-opening made as in the previous case near the lower epiphysis, the cavity disinfected and an iodoform-mesh introduced. It was changed once a week for five weeks and then discontinued as the wound looked perfectly healthy.

The wounds then closed rapidly. The patient has greatly improved, gained considerably in flesh. There is a good firm joint with free motion, shortening 1¼ inch. He has not been allowed to get out of bed yet.

Since operating these two cases I have found a similar treatment advocated in the *New York Medical Journal* of April 23, 1892, by Dr. C. T. Poore, of New York. He found the conditions described in 21 cases. In 11 cases he cleaned out the central cavity, introduced after disinfection a drainage tube in the counter-opening and the result was nine recoveries and two deaths, one 24 hours after the operation from shock, another three years afterwards from amyloid degeneration. Of 10 cases, in which the central cavity was not cleaned out, eight died and two recovered. In one of the eleven cases the whole shaft became enlarged, but has never given any discomfort.

With these results in view is it pertinent to ask, whether amputation is ever indicated in coxitis?

Discussion opened by Dr. Ridlon, of Chicago, who said that unquestionably in the majority of cases, the disease began outside the joint, in the bone and the difficulty of locating the focus of the trouble, raised the question as to whether it was best to operate or await the results of local treatment. Of course, if the patient is growing worse, operation is indicated, but otherwise, unless we can be sure we can remove all the diseased tissue and cure the case without relapse, within the time in which wounds usually heal, it is a question whether the operation should be done and the chances taken of septic infection through the sinuses leading into the joint or into the surrounding healthy tissue. His prejudices were against operating unless as a life saving measure.

Dr. Andrews, of Chicago, thought that in a large proportion of cases, after suppuration has commenced excision will be the best way out of the difficulty, though this may not be absolutely necessary to life, as has been shown by cases that have done well without excision. Such cases, however, recover more quickly after operation. Before the age of puberty there is very little danger from shock. He favored increased employment of operative procedures, but there are exceptions to all rules.

Dr. Mynter ascribed his excellent results to the great care with which he removed every portion of the diseased tissue, and also the fact that he did not try to get primary union and did not want it as he believed the wound did better if packed with iodoform gauze and allowed to granulate, as strong fibrous tissue then was formed and flail-joints avoided.

THE CREMASTERIC REFLEX IN VARICOCELE.

Read before the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, at Detroit, Mich., June, 1892.

BY THEODORE A. McGRAW, M.D.,
OF DETROIT.

I wish in this paper to make a short mention of certain observations and theories which I am not yet prepared to publish in full.

The accepted theory in regard to the causation and pathology of varicocele had never been entirely satisfactory to the profession. While it may be admitted that certain anatomical relations more especially of veins on the left side of the body may predispose to the disease, and while there can be no doubt of the occasional agency of injuries and venereal excesses in producing it, we must nevertheless acknowledge our ignorance of the exact pathological processes which lead to its development. We cannot explain why of two men of apparently similar constitution and habits of life one should suffer from the disease and the other escape. We may accept as the truth, the statement that the size, winding course and numerous anastomoses of the veins near the testis, their lack of support by the loose and inelastic tissues which surround them; the length and small size of their efferent trunks, the perpendicular course of the left spermatic vein and its right angled junction with the renal and its position under the sigmoid flexure render these veins especially liable to over distention and resulting disease. We may also agree that general debility, sprains, violent muscular exertion and excess of venereal excitement, conduce to the production of varicocele, and yet we have still to account for the fact that multitudes of men whose anatomical formation is precisely similar and who are subjected to the influence of all of these so-called causes, go through life nevertheless untouched by the disease. In other words, the alleged causes of varicocele do not in most people, produce varicocele, and unless we are willing to rest satisfied with the vague and unmeaning word "predisposition," we must confess that the essential factor has, as yet, escaped recognition. While we may admit that the particular conditions enumerated above, may influence though not in themselves determine the production of varicocele, there are other alleged causes which must be denied as not proven. Thus the often quoted absence of valves in the spermatic veins, is said by Curling, never to occur. He invariably found the valves to be present even though useless from over distention and enlargement of the veins. Whether the spermatic veins could be rendered varicose through the agency of muscular contraction or by the presence of hernia, tumors, trusses, abdominal belts, and the like must be regarded as more than doubtful.

It has seemed to me that certain pathological influences which affect the circulation of the blood through the spermatic veins have been too little studied in this connection. If we examine the theories which have been promulgated in respect to this disorder, it will be found that certain factors in the local circulation have apparently been altogether overlooked, although they have a most important bearing on the subject. If we omit all considerations of those factors of the circulation of the venous blood, which are common to the whole system, such as the action of the heart and diaphragm, atmospheric pressure and the like, we may say that the local venus circulation is furthered by three agencies: 1. The contractian of the venous walls. 2. The action of the nervous system, and 3. The intermitting pressure exerted on the spermatic vein by the contraction of the muscles which surround them, or are in their immediate vicinity.

In the walls of veins, like those of arteries, there are both longitudinal and circular muscular fibres and elastic tissues. These permit the veins to dilate under the pressure of the column of blood and to contract again, forcing the blood onwards. As long as the venous walls retain their tenacity, their contraction will form a most important element in the propulsion of the contained blood. On the other hand, any inherent or acquired defect in their mechanism, would of necessity, seriously impair the local circulation and lead, in itself, to the permanent and incurable distension of the venous walls. There can, in my opinion, be no doubt that many cases of varicocele are due to this cause. Local injuries, such as contusions and sprains may be presumed to act in this way by rendering the veins themselves incapable of performing their duty in forcing their contents on toward the heart. These are the cases in which the ligature by obliterating the vessels altogether, and compelling the blood to seek other and healthier channels, is most effeetive. The morbid area is here comparatively small, and if other more general causes of trouble are wanting, the operation is effective in causing a radical cure. In another class of cases, however, in which the seat of trouble is also in the venous walls, a cure is vastly more difficult and often impossible. In this class, a very small one, there is a general disposition to varices. The entire venous system would appear to be inherently defective, and the youth, affected in this way, will show early a tendency to dilatation of many veins. The veins of the scrotum, of the rectum, of the legs, and even of the arms will become thin and swollen. I have seen one or two cases of this kind and regard them as practically incurable, for you may obliterate the veins and cut off the scrotum, or do what you will, and the disease will tend to recur. It is remarkable, however, that when this tendency is acquired, later in life, as when old people become affected with varicosities caused by general vascular degenerations the spermatic veins generally escape, even though the the scrotal veins become enlarged. At least this is my experience in such cases.

It is uncertain in how great a proportion of cases the ætiology of the disorder must be sought for in primary disease of the venous walls. The disease is found only rarely associated with a general disposition to varices. "Landouz" found only one person in fifteen affected by varicocele who had also varicose veins of the legs, and of twenty other persons who had varicose veins of the legs, not one had varicocele, neither was he able to trace any connection between varicocele and hæmorrhoids. "Curling" confirms this statement from his own experience.

I have spoken of intermitting muscular pressure as a chief factor in the local circulation of the blood in the veins, and wish to emphasize its importance for the reason that it seems to have been lost sight of in the study of morbid conditions under consideration. The assistance given to the general venous circulation by the contraction of the muscles which are immediately adjacent to the veins is well understood. But the fact that the spermatic veins, are peculiarly dependent on muscular pressure for their support has seemed to have escaped observation. My own studies of this subject have led me to the conviction that every man would have a varicocele were it not for the action of certain muscles which continually urge the blood onward, and prevent undue distension of the spermatic veins. These muscles are, first, the cremaster; second, those of the abdominal walls, and third, the tunica dartos of the scrotum. Of these the cremaster is the most important, and it is very clear that its main function has been overlooked by anatomists and physiologists, who ascribe to it only one function, that of raising the testis. A mere superficial study of these muscular fibres, however, show that they afford a most powerful brace and support to the spermatic veins, and *assist, by their* contraction, most materially, in the circulation of the blood through those channels.

The cremaster muscle consists of a series of muscular and elastic fibres which seem to be a continuation of *the internal oblique.* They arise from Pouparts ligament, pass in a series of loops of various lengths, over and partly around the spermatic cord, and are attached to the pubic bone. The lowermost loops are fastened at the middle, to the testis. In a few instances loops have been found to surround the cord, but this is not common, although in all men they are so fastened to the sheath of the cord, that their contraction serves the purpose of a constrictor of the cord and its vessels. In some persons they are large, and in others small, and in a few, entirely wanting. They are usually most developed in strong, muscular men. They are connected together and to the areolar tissue of the cord by the cremasteric fascia, and their contractions draw taut the sheath of the cord, elevate the testicle and compress the spermatic veins. These contractions take place readily on any sudden irritation of the inside of the thigh and thus constitute the so-called cremasteric reflex, but they also occur from internal causes and irritations. Their action is assisted to some extent by the contraction of the tunica dartos, which shortens and corrugates the scrotum. The cremaster cannot contract without squeezing the blood out of the veins inclosed between its fibres in front and the inelastic tissue behind, which surrounds the spermatic cord, and which is firmly bound to the overlying muscular fibres. Caught between these opposing forces, the veins become emptied of their blood, to fill again the moment the contraction ceases. Now, this is the true and only important function of the cremaster. The testicle, by its weight, serves as a point of resistance, which enables the muscles to contract more firmly, and it is of course, raised whenever that muscle acts, but its elevation is only an incident in the exercise of the more important duty, which devolves upon the cremaster, that of propelling the venous blood upwards, and relieving, for a moment, the over-distended veins.

The force, which it exerts, acts from below, upwards, and the stimulus which produces its frequent and voluntary contraction, proceeds probably from the irritation excited in the veins by their over-distension. However, that may be, I do not doubt that the external support, which the muscle yields, is essential to the health of the venous walls and whenever it is wanting, especially in youth, whether from defect in the muscle itself or paralysis of the nerves which supply it, that condition is liable to develop which is termed varicocele. In more advanced life, the walls of the veins become firmer and less yielding and they can better withstand the loss of external support, for it is a curious fact, as I have already said, that these venous degenerations which occur in advanced life, and produce hæmorrhoids and varices of the lower extremities, rarely affect the veins in the cord, although not uncommon in the more superficial veins of the scrotum.

In the inguinal canal, the veins are exposed to the pressure of the ever-contracting abdominal muscles. Here again they receive an invaluable assistance in enabling them to perform their functions. The operation of this intermitting pressure is precisely that which occurs below when the cremaster contracts. During a muscular contraction, which narrows the inguinal canal the blood is forced from the contained veins in the direction of the least resistance, which is upward and inward. On the occurrence of muscular relaxation, they become again distended with blood, and the constant repetition of these movements, make a most important and indeed most essential factor in the venous circulation.

It is curious that this very muscular contraction of the abdominal muscles around the inguinal canal has been enumerated as a cause of varicocele, whereas it is doubtless if the circulation of the blood through the spermatic veins could take place without it, and yet it is very possible that the violent and spasmodic contraction of muscles may cause varicocele in this way. A vigorous young man engages in some struggle, such as wrestling or rowing, in which he puts forth all his power in one grand effort. The abdominal muscles contract with great force upon the structures in the inguinal canal and for the moment close entirely the spermatic veins, at the same time the blood is conveyed through the arteries in unusual quantity, and the veins below the inguinal ring become turgid and swollen. If now the cremaster is largely developed, and if at this very moment, it, in common with with other muscles, is put into a violent and almost tetanic contraction, the distended veins caught between the opposing muscles, with no outlet for the contained blood, either burst or stretch beyond the power of recovery.

In the one case, there will result an hæmatocele, and in the other a varicocele. It is probably in this way that these cases of varicocele occur, which are attributed to strain. The very vigor of the cremaster would here coöperate in producing a condition which is ordinarily the effect of cremasteric weakness.

As regards the third group of muscles, which aid the venous flow in the spermatic vessel, the muscular fibre of the tunica dartos, their action is comparatively weak and unimportant. They serve to make the individual more comfortable by holding up the scrotum and materially assist in the superficial circulation through the scrotal veins, but are not strong enough alone either to support the testis or the deeper veins which carry off the blood.

If now we ask how we can apply these pathological conditions to the study of varicocele, we may conclude that of these muscular groups, the abdominal muscles, whatever their condition as regards size, are ordinarily strong enough and act constantly enough to produce the intermitting pressure which is necessary to force the blood upward after it once enters the inguinal canal, while the tunica dartos is too weak in itself to make much difference in the circulation of the deeper veins. With some exceptions the cremaster alone is concerned in the pathology of such cases of varicocele as arise from insufficient muscular support. This muscle varies exceedingly in different men; in some it would seem to be nearly absent, and in these, from very childhood the testes hang low and the varicocele begins early, and in many cases on both sides. As soon as the sexual excitement of puberty begins, the veins begin to swell and the boy of fifteen or sixteen is already forced to wear a suspensory bandage. If the whole muscle is extremely defective, the cremasteric reflex may be altogether wanting. If only partly developed, we may believe that its defect will produce symptoms which would vary with the loops involved in the defect. Thus, if the long loops which descend upon the testes are present in sufficient volume, but the shorter loops which hug the cord are absent or very weak, the cremasteric reflex might be present in considerable degree and yet a varicocele develop in the veins from want of muscular support, while on the contrary, the presence of the shorter loops might prevent venous disease, even though the testicle itself dragged upon the cord, though the absence of the longer loops which should be attached to the organ and lift it up. There is hardly any anomaly of development which one could think of in regard to this muscle which might not be present, and producing peculiar conditions. The presence of the cremastic reflex therefore would not necessarily indicate the existence of an adequate support to the spermatic vein nor its absence indicate that that support was altogether wanting. Neither would the absence of the cremasteric reflex and the development of a varicocele necessarily prove that the disorder arose from a congenital deficiency in this muscle, for an acquired paralysis would effect the same result.

I am inclined to think those cases of varicocele which are ascribed to excessive sexual excitement may be due to a paresis of the nerve which supplies the cremaster. I have never met with such cases myself but find recorded in practice. One physician told me he had seen four cases which developed in young men immediately after entering upon engagements to marry, presumably due to prolonged ungratified sexual desire. Whether in such cases, there may be any inherent weakness of the nerves or the muscle itself, must be uncertain, but that sexual excitement alone could not produce the disorder, is sufficiently demonstrated by the experience of the vast majority of men.

Varicocele will make its appearance sometimes in connection with obscure trouble of the nervous system. Dr. Imrie kindly sent a young man of sixteen years to me, with a varicocele of the left side, of some three months' duration. A Jew, he had been circumcised in childhood, both testes hung equally low, and as far as the cord would allow. The cremasteric reflex on the right side could be elicited with difficulty and on the left not at all. There was a double varicocele most developed, however, on the left side. The knee reflexes were also wanting and he had suffered for three months from incontinence of urine. I saw the case but twice and was therefore not able to study it as I could wish, but it was evident that there was here a paralysis, possibly of spinal origin associated with and probably causative of varicocele. It is possible that reflex irritations like those produced by narrow foreskins or by intestinal worms, may produce the same result. As showing the connection between affections of the cremaster and those of the testes and cord, I may here mention a case now under my treatment of neuralgia of the testis in a man 46 years of age: it began a year ago without apparent cause, in the left testis and of late has occasionally affected the right; the testis is quite tender and sore, though to the touch not perceptibly altered from the normal. The pains which are nearly continous are chiefly in the testis and cord but sometimes affect the small of the back. I suspected some spinal sclerosis but could not verify that hypothesis, as his knee reflexes were normal and he had no other symptoms. His urine contained nothing abnormal. Now, he had this peculiarity; he had been able to control his powerful cremasters perfectly and jerk his testicles up at will with great power; he did this in my presence, on the right side and I was astonished at the vigor of the contraction. On the left side, however, the ability to raise the testis had failed him and he could produce a contraction of the left cremaster only by moving the two together. Then the contraction of the right muscle had nearly ceased, one could see an imperfect movement of the left. The cremasteric reflex on the right side was prompt and strong; that on the left could not be elicited at all. I fancied that the left veins were slightly swollen and have no doubt that had he been twenty instead of nearly fifty, he would soon have developed a varicocele.

While there are not a few varicocele in which the cremasteric reflex is nearly or quite normal, in the majority of cases, patients show a decided disturbance in the mechanism which produce it.

In how many cases this is due to congenital effects of the cremaster and how many to paralytic conditions, or acquired weakness, I am unable to determine from my inability to complete my observations by the necessary dissections.

It is not easy to obtain autopsies in persons subject to varicocle and I have failed in my efforts in that direction. In operating however, on a living subject for varicocele, I have noticed carefully the conditions of the cord and its coverings and have rarely found a well developed and powerful cremaster, in marked contrast with cases of scrotal hernia, in which the fibres of the cremaster are often enormously hypertrophied.

It is interesting in this connection to study the relations of hernia to varicocele, and more especially as my observations have led me to take issue with some authorities, who have ascribed to hernia the power of producing varicocele by pressure on the efferent veins of the testis.

I can recall only two cases from my practice in which hernia was associated with undue enlargement of the spermatic veins. They were both cases of small hernia in young men of weak muscular fibre, and in both there could be no pressure on the efferent veins by the easily reduced, small protrusions sufficient to cause venous disturbance. It was evident that both disorders were induced by the same muscular insufficiency.

On the other hand, in operating on very large irreducible scrotal hernia, I have had occasion to remark as have many surgeons, the great size and large number of the veins around the hernia. I have never regarded these enlarged veins as at all allied in pathology to varicocele. In the first place, the veins in the testes proper rarely are very much larger than common. The hypertrophy, for I consider it such rather than a varicosity, affects principally the veins of the covering of the testes, those which carry back the blood of the cremasteric and pudic arteries, and while the veins are very large and numerous, they are not more so than is necessary for the nutritive processes of these enormous protrusions and the hypertrophied tissue, which surrounds them. Such patients have none of the subjective symptoms of varicocele, their testes are not atrophied, and I have no doubt that the cure of the rupture, if it were possible, as it rarely is, would be followed by the gradual recurrence of the veins to their normal condition. On the other hand, hernia and varicocele are both so common as disconnected disorders and are so rarely found present in the same individual as coincident disorders that one is almost forced to conclude that there is some antagonism, so to speak, between the two. I believe that this is the case and that the reason of it is to be found in the processes which take place in the development of the testes. According to Curling, the gubernaculum testis exists from an early period of fœtal life as a soft cord of connective and muscular tissue which extends from the lower-most point of the testis by three divisions to the inside of

Pouparts ligament to the os pubis and to the bottom of the scrotum. He belives that the testis is guided into the inguinal canal by that part which is attached to Pouparts ligament, is pulled through the canal by the pubic portion and is finally drawn into the scrotum by the scrotal portion. In its passage through the inguinal canal, some fibres are detached from the internal oblique muscle and form the loop which lies over the front and sometimes around the cord. It is these loops especially which give support to the veins, and aid in the propulsion of venous blood through them, and a moment's consideration will show that if this description of the process is correct, the strength of the walls of the inguinal canal will be inversely to that of the cremaster. If there are only a few fibres detached from the internal oblique the inguinal wall will be stronger, if many are carried down it would, of necessity, be weaker. But strong walls mean less danger from hernia, while a large cremaster means freedom from the liability to varicocele. It is easy to suppose, therefore, that such individuals as are liable to inguinal hernia are less liable to varicocele and vice versa. At the same time, it would not exclude the possibility of both diseases occurring in the same individual, if he were a man generally deficient in muscular development. I have been much disposed to doubt all these theories which refer the development of varicocele to pressure of any kind.

The effects of pressure are ordinarilly felt only when pressure is long continued and the disease which arise from pressure,therefore commonly occur in middle or old age,and we see this exemplified in hæmorrhoids and varices of the legs,which, though not unknown in young persons, are far more common in the aged,but it is notorious that varicocele is a disease of youth and makes its appearance at an age when hæmorrhoids and varicose veins are rare indeed. The pressure of the sigmoid flexure on the left spermatic vein, which is one of the alleged causes of varicocele, must be vastly greater when the gut is filled with long standing accumulations of fæces, such as occur in cancers and strictures of the rectum than in the occasional constipations of youth, and yet, whoever knew a varicocele to arise from that cause. The constipations of middle aged and old men cause hæmorrhoids,but almost never varicoceles. This has been with me so uniform an experience, that I am disposed to conclude that theories which refer varicoceles to such causes are due to imperfect observations.

It is, indeed, a question whether the pressure of the bowels on the spermatic veins would not act rather beneficial than detrimental to the circulation of the blood through them. In the first place, they conduct the intermitting pressure of the abdominal muscles through to the veins, and this must be as we have seen, a great aid, and in the second place, they themselves would subject these vessels to an intermitting pressure, as gas and fæces pass through the gut in ever varying quantities. Only in conditions of chronic, irremediable constipation, conditions uncommon in young men, could a bowel exert that dead, unyielding pressure on a vein which would cause distension of its distal portion. That the left spermatic vein is ever subjected to that kind of pressure, even when the sigmoid flexure is loaded with impacted fæces is a question of great doubt. That the left vein is more frequently affected with varicocele than the right would seem to me to be the result rather of general than of local condition. The whole left side of most men is weaker than the right. The left foot is smaller. The left muscles are weaker. It is possible that the left cremaster, under this same law is in the vast majority of persons, much weaker than the right, and that the left testis hangs lower for the same reason. It is possible, too, that the walls of the veins themselves on the left side may be weaker and less developed, and the vessels of the left side may be weaker and less developed than the vessels of the other side of the body.

To conclude with the summary of this paper, I should say:

1. That the pathology of varicocele is variable, cases differing from one another both as regards causes and pathological conditions.

2. In one group of cases, the fault lies in the walls of the veins which have become weakened either by injury or from congenital or acquired disease. In this group, the cremasteric reflex may be altogether normal.

3. In another class of cases, the primary diseases involve either the cremaster or the nervous mechanism by which it is controlled. The muscles may be congenitally defective in volume or abnormal in position, or it may be entirely wanting, or, on the other hand, it may be either temporarily or permanently paralzed. Whatever the nature of the original affection, these cases are marked by deficiency in the cremasteric reflex, which, in some cases may be altogether wanting, and in others, very weak and uncertain. As the greater proportion of varicocele shows this symptom,it is fair to conclude that the majority of varicoceles are due to affections of the cremaster. It is important that the whole subject should be studied anew, in the light of pathological anatomy, and it will be well for those who are so fortunate as to secure autopsies in persons so afflicted to bear the matter in mind.

Dr. Mynter, of Buffalo, asked whether the knowledge that the cremaster muscle may influence the production of varicocele would have any bearing on the treatment.

Dr. McGraw replied that if we considered the varicocele due to paralysis of the cremaster muscle, electricity might be used, but when the cremaster is wholly absent removal of the scrotum is the best treatment, though this support cannot make up altogether for the intermittent support of the cremaster muscle.

Dr. De Garmo, of New York, said he could confirm two points. He had very carefully watched the effect of pressure as a cause of varicocele and had seen many cases with hernia, but did not think it had anything to do with the production of the former even where bad trusses were worn. He did not recall any case coming on late in life and had never seen a case from strain. In considering the relation of hernia to varicocele he reported a case which he had had under treatment for two years for hernia. It was operated on by another gentleman for varicocele and the hernia was cured. With regard to operation he had used the plan of passing a silk thread round the veins and tying them off. He had had excellent results, no accidents, and no recurrence.

Dr. McGraw concluded by saying, that as his paper had reference only to the pathology, he refrained from saying anything about the treatment.

THE OFFICERS of the Association of American Physicians for the ensuing year are as follows: Alfred L. Loomis, New York, President; R. H. Fitch, Boston, vice-President; I. Minis Hays, Philadelphia, Recorder; Henry Hun, Albany, N. Y., Secretary; W. W. Johnson, Washington, D. C., Treasurer.

THE MANAGEMENT OF GANGRENOUS HERNIA, WITH REPORT OF A CASE.

Read in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY JOSEPH RANSOHOFF, M.D.,
OF CINCINNATI, O.

Nothing more clearly demonstrates the evolution of surgical thought and practice than a comparison of the questions deemed of prime importance in relation to strangulated hernia at the extremes of two decades.

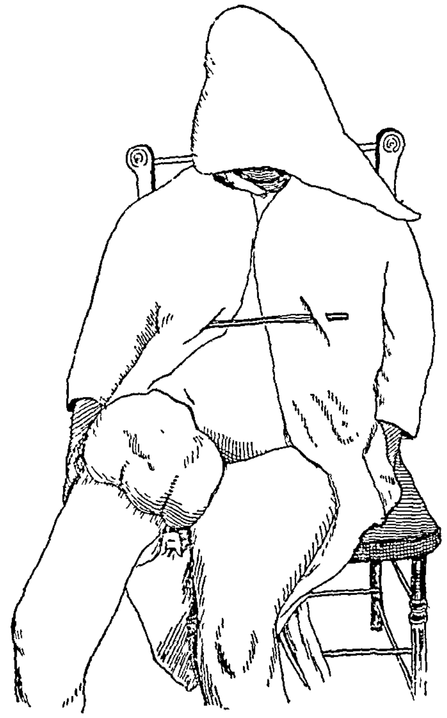
Prior to 1870, the question to be answered in every case was "Is the sac to be opened, or not." At the present, a condition is hardly to be conceived in which the operator would refrain from opening the peritoneal tunic, thoroughly inspecting the hernial contents and wherever feasible supplementing the relief with the radical operation.

Taxis, which then played so prominent a rôle in all cases has been accorded a more and more subordinate position, as its dangers ever increasing with the age of the strangulation were more fully appreciated, and in proportion as surgery sought the light for its manipulations in large and open wounds. Then, the teachings of the German and English schools regarding gangrenous hernia prevailed. The oft-encountered sloughing gut was incised and permitted to drain as an abscess. Now the really vital lesson of kelotomy, that in its early performance lies its safety, has been widely learned. Therefore gangrenous hernias are becoming relatively less frequent. Of 27 cases which have come under my observation, only 4 were gangrenous. Three times have I seen gangrene of the intestine; once of the mesentery alone. In one of the former, the strangulation had existed less than 24 hours. Of 170 kelotomies for strangulation in Hagedorn's Clinic[1] (*Z. f. Chir.*, 32, p. 356) gangrene, real or suspected was encountered but 25 times. In Gottingen Konig[2] had 49 strangulations in 5 years, gangrene being present in 8. Of 61 cases occurring over a period of 12 years in Czerny's[3] Clinic 15 were gangrenous. Of 94 cases operated on in the Mass. General Hospital[4] 7 were gangrenous and 2 doubtful. F. A. Southern of the Manchester Royal Infirmary reports 85 cases of hernia and among them 9 of gangrene. Thus of 486 cases occurring within about twenty years only 68 or about 14% were gangrenous or doubtful cases. Clearly therefore the experience with this condition of any one man, unless disposing over an unusual clinical material, must be limited. It is therefore by cumulative evidence that the proper management of this most fatal complication of hernia must be evolved. In this belief I venture on the report of the following cases:

Case 1.—Walter P. aet. 29, farmer, Carlisle, Ky. Rupture of several years standing. Truss worn, but irregularly. While at work strangulation appeared on the first of August, 1889. Continued work for some time and attempted reduction. After 48 hours Dr. Tilton was summoned but taxis failed. The necessity for an immediate operation was urged but it was declined. I saw the patient on the night of the fifth day. Abdominal distension marked. Obstipation; vomiting frequent but not feculent. Pain severe about umbilicus. Great restlessness. Temperature 102°, pulse 100 and full. Scrotal hernia size of fœtal head; hard and without impulse on coughing. Skin red and œdematous. Operation by lamplight. In the hernial sac was fully a half pint of foul-smelling bloody serum. Omental mass as large as a fist, of dark brown color, putrid and friable; no adhesions to sac. (The latter was a dusky blue in color.) There was no intestine in the hernia. After carefully cleansing the sac and its contents and covering the protruded omentum in gauze, the constriction at the internal ring was divided. The omentum was easily drawn into the wound, after severing some slight adhesions. It was ligated and returned to the abdominal cavity. Thorough intra-abdominal drainage through the wound was provided for. Death 24 hours post-operation from peritonitis. An autopsy was not made.

Case 2.—Mrs. M. aet. 69. Hernia of 15 (?) years standing. Has frequently had symptoms of fecal impaction. After a supposed attack of this kind had lasted three days, Dr. J. Marcus was summoned. I saw the patient in the evening of the fourth. There had been fecal vomiting for two days. Aside from a decided dyspnœa from which the patient suffered at all times the general condition was not good. There was no elevation of temperature. Pulse irregular.

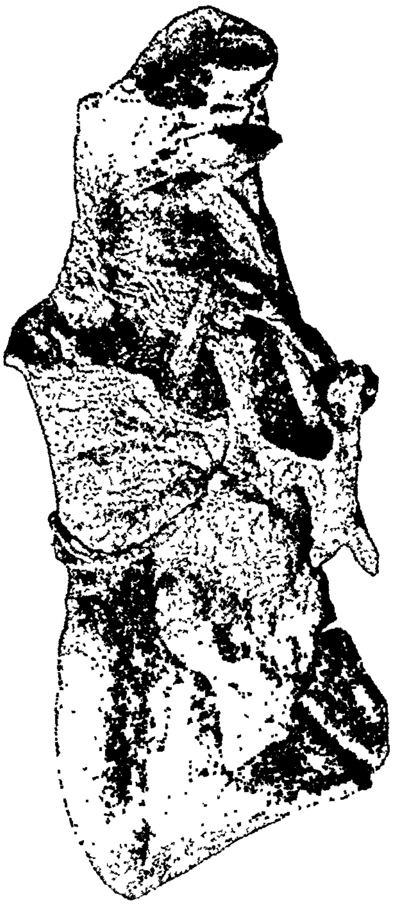
The appended illustration displays the woman's femoral hernia. Large and lobulated it covered the entire upper and lower part of the thigh. Transverse measurement, 11 inches; longitudinal, 7 inches. The greater portion of the hernia was soft. In its depths there was an indefinitely outlined mass which was painful on pressure. Believing the case to be one of impaction within the sac and recognizing the gravity of an operation under the conditions present, the patient was anaesthetized with a view to operation if taxis moderately used did not overcome the difficulty. That I did not operate at once was a fatal error. With very little force gurgling was elicited and the mass before mentioned seemed to have subsided. After coming out from the narcosis, the patient's condition was found to be unrelieved. When I saw her the next day, she was moribund. Exit lethal 16 hours, post-operation.



Autopsy.—On opening the sac it was found to be multilocular. The many diverticula evidently resulting from the lesser resistance of the meshes between the denser fibers of the cribriform fascia. The coils of intestine were for the most part as freely movable as in the abdomen. In one of the saccules an obstruction was found. It was produced by a band as large as a quill. It sprang by a broad base from the free border of a coil of intestine and was attached to the under surface of the mesentery of the same coil. In the loop thus formed a second coil had become entangled. Above and below the constriction-furrow the bowel was normal. In the constriction groove itself a localized gangrene or rather pressure necrosis had led to a perforation. The aperture is about one-sixth of an inch in diameter; and on the free border of the intestine. There is no fecal extravasation.

The band springs from the ilium about 14 inches from the ileo-cæcal valve. It presents a central cavity which tapers off towards its mesenteric attachment. The character and position of the band make it certain that it is a Meckel's diverticulum. Though often producing intestinal acute obstruction in the belly cavity, I have not been able to find the record of a case where it had given rise to obstruction in a hernia. In this regard the case presented is unique.

Case 3.—Miss D., æt. 30. Seen with Dr. Jenkins, Newport. No previous history of rupture. While lifting a mattress felt something give way in the groin, four days before operation. Was seen by Dr. Jenkins on third day when taxis was attempted. Then vomiting became severe and abdominal pain intolerable. An operation was permitted. Hernia large as a walnut. No impulse on coughing, not very tender. Absolute obstruction since inception. Abdomen not distended. General condition very good. On opening the sac several ounces of bloody serum escaped. There presented itself a knuckle of small intestine apparently of the ileum about four inches long, of bluish color and moderate distension. The serous covering was glistening.



Gangrenous Hernia. Constriction by Meckel's Diverticulum.

In the center of the coil opposite to its mesenteric attachment, there was a black gangrenous patch large as a silver quarter and circular in outline. After carefully cleansing the sac wall and intestine, the constriction at Gimbernat's ligament was divided and then brought into the wound. Although the constriction furrow was unusually deep there was no evidence of present or probable necrosis. The afferent bowel was considerably larger than the efferent coil but presented a healthy appearance. Indeed during the few moments that the hernial contents were being studied with a view to definite action the circulation returned to all of the gut save the gangrenous patch alluded to. It was finally determined to return the entire intestine to the abdominal cavity retaining by two catgut sutures passed through mesentery and wound margins, the gangrenous surface in absolute relation to the floor of the wound. The latter was lightly packed with gauze, and a sterilized dressing applied over all. The vomiting continued for several hours. Ten hours after the operation the patient had several large and watery evacuations. On the fifth day perforation of the intestine ensued and during two weeks the large portion of the intestinal contents discharged through the fistula. Without other treatment than compression the aperture gradually contracted and in a little over a month had entirely closed. The process of sloughing was unattended by either local or general reaction. The patient has since remained well.

Case 4.—Mrs. K. Seen with Dr. Harff. Patient, æt. 56, was for many years the subject of an irreducible inguinal-labial hernia of the right side. Has repeatedly suffered from incarceration. Once reduction was accomplished under anæsthesia. While at work on Friday morning, she experienced a sudden and excruciating pain in the hernial protrusion and suffered immediately from nausea and vomiting. Saw the patient twelve hours after first symptoms supervened.

The hernial protrusion, large as a cocoanut, was soft and resonant throughout. Impulse on coughing plainly perceptible in many parts of the mass. From the base of the hernia projecting towards its surface a coil of intestine could easily be outlined and palpated. It was dense, hard and persisting; like a link of tightly packed sausage in shape and to the touch. Diagnosis strangulation by band; gangrene probable notwithstanding the excellent general condition of the patient. It was nearly midnight when I saw the patient, and necessary assistance was not at hand. The operation was therefore deferred until morning. During the intervening ten hours very extensive effusion into the sac had taken place. The constricted coil could no longer be clearly outlined.

Incision ten inches long in axis of tumor. On opening the sac some half dozen pouches connecting with it were exposed and in them were coils of bowel and adherent omentum. The sac presented the usual appearance of an old irreducible hernia. In one of the compartments near the greatly enlarged ring a loop of the bowel had become fixed by a band. The sac, separated from the general cavity, when opened discharged six or eight ounces of a foul bloody serum. Within it was a coil of gangrenous bowel. Completely sequestering with gauze the infected area, the constricting band was divided and the sloughing gut brought into the wound for inspection. Along the line of constriction a deep groove had been formed but there was no necrosis. The coil itself was of a dark chocolate color and lusterless. Under its surface, which presented few abrasions, were many hæmorrhagic extravasations, chiefly near the border. Perforation had not taken place. Above and below the constriction groove the intestine seemed normal.

The patient's general condition warranting the procedure, primary resection was determined on. Having thoroughly protected the wound, and brought the intestine well down, a gauze cravat was lightly drawn through mesentery an inch above and below the constriction groove. Excision followed, the mesentery being divided a short distance from the gut and parallel to it. Hæmorrhage from the mesentery was free, but no ligatures were required. As the mesenteric wound was brought together by a continuous silk suture beginning at its centre and including its entire thickness, the bleeding points were included within it. When completed the mesenteric suture line measured about four inches. As this suture progressed, the intestinal ends naturally approached each other. No clamp was used, the fingers of an assistant answered admirably. The ends were of uniform diameter. For suturing fine silk and an ordinary cambric needle was used. The suture employed was the continuous Lembert. Particular care was taken at the mesenteric attachment. When completed the suture appeared weak at two points. These were fortified by additional sutures. The sutured bowel was returned to its sac, the wound thoroughly irrigated and closed except for gauze drainage at its most dependent portion. Time of operation fifty minutes. Length of gut removed fourteen inches. Union primary, and recovery uninterrupted; nineteen months have passed since the operation. The patient continues well.

The first case presented is of interest in that the omentum is rarely involved in the sloughing process of a gangrenous hernia. B. Schmidt [6] questions altogether the existence of primary strangulation of the omentum. Of Nagedoms 170 cases, gangrenous omentum was only once the sole occupant of the sac.[7] I have found reports of two other cases, one from Heidelberg; [8], the other of W. H. Bennet [9] of St. Georges Hospital. The safety of the omentum from gangrene is readily found in the ease with which it forms adhesions to the sac wall through which it then receives its nutrition. The case first reported appears to me to put a quietus on the theory long advocated and recently again promoted by Banks, namely that the constriction ring should not be divided in most cases of gangrenous hernia on the ground that it is a bar to the development of general peritonitis. By the constriction the septic products of the hernia may be isolated for a time. But peritonitis develops from within. In the case presented there was no communication between the sac and the general belly cavity. But just within the neck was the large gut fixed by the adherent omentum, and its wall rendered paretic though traction was unable to resist the passage through it of the organisms which fatally infected the peritoneum. Fortunately there can be but one opinion as to the management of gangrenous omentum. Excision after ligation in healthy tissue, and return to the peritoneal cavity will generally end in recovery unless peritonitis already exists. The three cases quoted all recovered, although in each the medical operation followed that for strangulation. The wisdom of this procedure in all cases might be seriously questioned. In severe cases where peritonitis already exists or is threatened, the last step might advisedly be refrained from and thorough drainage secured. At all events capillary drainage through gauze can never be harmful. It may be relied upon to forestall the development of a peritonitis and where the process already established is yet local, evert a fatal issue.

When gangrene involves the intestine the solution of the problem is far less easy. Since Ramdohr first successfully resected the gut for hernia in 1727, the possible success of primary excision has been conceded. Of recoveries there have been many. But the measure however ideal has never gained firm footing among surgical procedures. This in face of the fact that the results from the alternative measure, that of the formation of an artificial anus, have been most deplorable. Recently Poulsen reports 29 [10] cases with but 4 recoveries. Of thirty-five cases so treated at St. Bartholomews, 4 were saved. (*Brit. Med. Jour.*, 1891, I., p. 701.) Certain is it that all cases should not be treated alike and that every case ought to be considered with reference, first to the condition of the intestine and its environments and second the probable ability of the patient to bear the shock of a prolonged operation.

In three of the cases presented many of the changes except those of the afferent portion of the bowel were found. For a strangulation affects the gut either along the line of constriction; at some or all points of the coil involved or in the course of the intestine for a varying distance above the point of constriction. Where the constricting band binds the gut, a well marked groove is made by direct pressure. The constriction tight enough to occlude the calibre of the bowel may not interfere with its vascular supply. If gangrene results it will be from pressure at the bottom of the groove and limited in extent. Except for the usually small ulcer in the constriction groove, the gut above and below may be normal in appearance. In the fruitless efforts of nature to protect the general peritoneum, adhesions are quickly formed between bowel and neck of sac. In the attempt to sever these the fragile wall of the bowel tears along the line of constriction. Doubtless many cases of this kind occur, the fecal outpour taking place at the time of operation. To avoid this it might be wise to follow the practice of Mikulicz [11] who in every case of suspected gangrene opens the ring from within the belly cavity, thus making a laparo-kelotomy which permits as he thinks thorough isolation by gauze of the infected area. The difficulty appears in the fact that pressure gangrene limited to the furrow and made by the constricting band is not always easily recognized. Fortunately the tissues about it whether torn by manipulation or not are in a fair condition for partial excision and lateral suture, by which the patient may be saved the perils and annoyance of an artificial anus. Krumm reports such a case successfully treated and Barette three of pressure gangrene successfully managed in the same manner.

The deleterious effects of strangulation are not equally visited on all parts of the coil. In some cases, as in the fourth presented, the entire knuckle is [illegible] dull-chocolate or grayish color, with or without [illegible] hæmorrhages. It is soft, friable, gangrenous throughout. In others as in the second the force of the strangulation, although influencing the circulation of the whole, appears to effect most seriously the central part of the knuckle and at a point removed farthest from the mesentery. It is clear that if in such a case excision were to be done it could only be beyond the limits of constriction. The cyanotic gut about the really gangrenous centre would ill support a suture. Let alone, it will recover. The handling incident to suture might easily prevent it. Furthermore, in cases of this nature the gangrene is often more extensive than is apparent. Beginning generally in the mucosa, the serous tissue is the last and therefore least affected. The fixation of the gangrenous area in the bottom of the wound, relying on nature to make the anus preternaturalis appears to me sound in judgment. The data on which this view is based differ from those which militate against the formation of a fecal fistula when the gut is gangrenous in its entirety.

First and foremost the calibre of the gut remains patent and death from inanition is rendered impossible. Again the artificial anus which results will probably be small and close in a few weeks or months without operative interference. Where the gangrenous area is surrounded by healthy tissue and sufficiently small it may be excised and closed as would be a gun shot wound, or it may be united as suggested by Lindner [12] and closed by sutures holding the contiguous parts together in horizontal fold. Of the former practice and lateral suture Barette [13] reports 24 cases with 21 recoveries. Sachs [14] reports a case similarly treated with success.

INTERNATIONAL DERMATOLOGICAL CONGRESS.—The second Dermatological Congress will be held in Vienna from September 5 to 10, 1892.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.
All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, AUGUST 13, 1892.

DISEASE AND CRIME DUE TO HOT WEATHER.

It is a well known fact that petty crime particularly against persons, follows the rise and fall of the temperature with startling uniformity. The late heated term has illustrated this fact in every city and town of the country.

Wherever spirits are sold most of the offenders were intoxicated, or more literally made delirious by the poison of alcohol. Persons accustomed to use spirits are more susceptible to the narcotic effects of alcohol at this time, and manifest unusual irritability and want of judgment. Persons who are not alcohol drinkers exhibit equally strange mental symptoms. This year the number of heat prostrations and sudden alarming exhaustions incident to this condition have been greatly in excess. Transient delusions, severe neuralgias and digestive disturbances have been common. The influence of the late epidemic, influenza, has been traced in many cases. One physician reports that in ten cases of heat prostration, eight were traceable to the effects of influenza, which prevailed from one to six months ago. This sustains the observation of others, that nearly all cases of influenza leave a susceptibility and predisposition to take on diseased conditions from the slightest exposure. The effect of extreme heat is generally understood to favor the formation of poisonous products in the body, and require extreme perspiratory activity in the process of elimination. If the skin and glandular system are defective and do not respond to the demands for increased activity, these products are retained and become active poisons. This is only one of many potent factors which conspire to derange the normal activity of the body in such periods. Why criminal impulses are more active, and less under control in seasons of unusual heat, is not yet clear. The real explanation must be along physiological lines, and facts that show the physical basis of crime. Among alcoholics, the unusual action of spirits on the brain, first irrigating, then narcotizing the brain centers, more profoundly and rapidly at this period is the common observation. But why persons who do not use spirits should give way to impulses at this time, which they are able to control in cooler weather, is a mystery. To say that the brain centers are more unstable, and have less resisting power; also that states of hyperæmia are present predisposing to these abnormalties, is not a full or very satisfactory explanation. The fact to be recognized practically is of more importance than the theory of causation. Viewed from its medical side crime committed in these hot seasons, points to physical conditions that are not reached by locks and bars. Many of these criminals need active medical care more than punishment.

There are many and preventable causes that can be known and reached in this field. Disease following and dating from injury due to periods of excessive heat, suggest to the thoughtful physician different therapeutical lines of treatment. Crime evidently dating from, and due largely to the same cause, is treated as more culpable by the courts. The quiet, inoffensive man who suddenly on a hot day, without having used spirits, becomes angry and assaults some one, is suffering from brain disturbance. A man equally quiet and unobtrusive, feeling bad on a similar hot day, drinks some spirit mixture, and soon after commits assault, or theft, or breach of the peace, or abuses his family, or horse, etc., etc., is suffering from similar causes, and needs medical treatment.

Physicians should study and educate public sentiment to recognize the physical and medical side of these cases. The experience of the recent heated term, if gathered up by competent students, would furnish a chapter of remarkable facts of the most intense scientific interest. These facts are more apparent in the northern and western States, than in the south, and have a direct bearing on the crime wave theory which seems so often supported by statistics.

This theory assumes that crime is due to cosmical and physical causes, which at long intervals gather and burst like storm clouds, then die away to a minimum. A prolonged heated term brings out a vast number of corroborative facts, and also points out apparent causes which seem to be active factors. The teachings of science show that disease and crime are literally interchangeable terms, and the relation is very intimate. Now if certain extreme changes of temperature are followed by increase of one or both, this fact indicates the operation of physical laws that should be studied and understood. Almost every active medical man in the country can contribute facts bearing on this question. Let every physician inquire into the crime and disease of his neighborhood that was dependent in whole or in part on the extreme hot period just past. Also the influence of the epidemic influenza in the past, and alcohol, with all the various unsanitary conditions which favor degeneration and debility.

From the accumulation of numerous facts of this character, many valuable deductions may be drawn, together with practical hints for prevention and treatment.

THE MANAGEMENT OF THE COMPLICATIONS OF POTT'S DISEASE.

Deformity, abscess, and paraplegia are the only complications of Pott's disease occurring with sufficient frequency to merit especial consideration. The management of these complications at the present time is much as follows:

Deformity may be more or less corrected in those cases where the reparative action has not yet reached the stage of appreciable consolidation; or it may be accepted. For correction of the deformity three methods are employed: 1. *Immediate redressment* by longitudinal and antero-posterior traction with weights and pulleys, the patient lying prone, followed by immobilization with the "shell-back" cuirass (Blanchard); 2. *interrupted redressment* by partial vertical suspension repeated at intervals of a few weeks or months, the spine being immobilized during the interval with the plaster jacket (Sayre); and 3, *gradual redressment* by continuous action of the antero-posterior leverage brace (Taylor). The circumstances surrounding the individual case should decide the choice of method.

It appears that reparative action is delayed by the corrective process and that permanent consolidation does not take place until immobilization has become continuous and complete. For this and other reasons the majority of surgeons accept the deformity present and immobilize immediately from the beginning of treatment without any attempt to correct the deformity.

Abscesses so located as not to interfere with the application of the immobilizing apparatus and causing no constitutional symptoms have been generally left without interference, but recently there is a growing tendency to aspirate if it is possible to reach the abscess before it has attained any considerable size and inject the cavity with an aseptic mixture of iodoform in glycerine or olive oil. Large abscesses may be opened, their cavities cleansed, injected with the iodoform mixture and closed without drainage. A few remain closed and heal, many refill and opening spontaneously are in no better and no worse condition than if left without interference, and a few become infected and seriously threaten the patient's life. Permanent drainage of these abscesses by the insertion of a tube into the opening adds to the chances of infection and prolongs indefinitely the final closure of the sinus. Without strict asepsis operative procedures should not be attempted; with strict asepsis drainage is unnecessary.

Motor paraplegia requires no special treatment. The area of the diseased spine should be immobilized, the patient should be kept continuously recumbent, and if occurring early in the disease, longitudinal horizontal traction may be employed. Cauterization over the kyphosis is cruel and useless, and the enormous doses of iodide of potash recommended some years ago by Gibney are of very doubtful benefit except in cases where there is a strong suspicion of inherited syphilis. Nearly all cases treated by immobilization and recumbency recover from the paraplegia within from one to three years. Paralysis of sensation as well as motion adds much to the seriousness of the complication. Lamnectomy is justifiable, but less benefit is now anticipated from it than was looked for when the operation first came into vogue. Most cases suffering from sensory paraplegia as a complication of Pott's disease ultimately succumb.

EDITORIAL NOTES.

Foreign Bodies Left in the Abdominal Cavity.—The abdominal walls and cavity display at times a tolerance to surgical manipulations that sets at naught the preconceptions of all students of the authorities. In one respect, however, this tolerance is not very liberally displayed—when foreign bodies, inclusive of articles used by the surgeon, are left behind in the peritoneal cavity after an operation. But even instances of tolerance in this respect are not unknown, where the patient refuses to die even although such an article has been left within the sewed-up wound of a laparotomy. From a Paris letter to the *Medical Press and Circular*, we learn that Dr. Pilatte presented to the Société de Chirurgie a compress of antiseptic gauze that had been detained in a patient's abdomen for eight months. A laparotomy was done upon this woman in April, 1891, followed for a number of weeks by a fair recovery, until in the following August, when pain began to declare itself in the abdomen. The pain grew progressively worse through October and November, until finally, inDecember, the patient passed by the rectum a roll of gauze fully 8 inches long, which must have been forgotten or overlooked after the laparotomy. Since the escape of the roll of gauze, the abdominal pains have ceased. M. Quénu stated that a similar incident had occurred in his practice. A woman was being operated upon by abdominal section, when a fainting fit made him and all his assistants direct their attention to the cardiac and respiratory needs of the patient. A compress that was used to prevent an escape of the intestines was drawn into the abdominal cavity, and hidden from view by the movements of the woman. The surgeon was assured by his assistants that none of the surgical materials was missing, before he proceeded to close the wound. On the fourth day, however, the patient died. An autopsy was had, and the compress was found twisted in among the intestines. Ever since that time M. Quénu has kept an accurate count of the compresses, as well as of the sponges, that are used in his operations. M. Terrier said that one of his associates had recovered a pair of forceps after a lapse of eight months. The instrument worked its way out through the umbilicus, and the patient got well. He had himself lost a sponge through a failure to keep a strict count, and the patient lost her life by peritonitis in consequence of the oversight. There are very few surgeons, in the present day, who do not tally off their sponges both before and after an operation. But even this precaution may not avail; it did not suffice on one occasion at least, for a too enthusiastic and helpful nurse tore a sponge in two, and thus caused the count to miscarry. Of all the materials employed by the laparotomist, his sponges are the ones he is most anxious about, since they are the most readily overlooked, and have been overlooked by some estimable and cautious surgeons. These incidents, or accidents, cause chagrin to the surgeon even if the patient's life is not lost thereby; for the patient's road to recovery is greatly hampered by the weeks and months of intense suffering that ordinarily ensue while nature is endeavoring to eliminate the offending body. Extreme vigilance in this regard is the price paid for the best results.

Symptomatic or Secondary Forms of Appendicitis: Paretic Distension of Cæcum.—An admirable paper on appendicitis, as a symptom of distended cæcum, is to be found in the *New York Medical Journal*, July 16, by Dr. P. C. Barker of Morristown, N. J. The author has made it his practice for thirty years to notice and study the cæcum and appendix in every available case of abdominal section. It is his observation that the orifice of the appendix is not always easily discoverable from the mucosal aspect, even when the bowel has been fairly laid open. It is sometimes necessary to search around with the probe point before the orifice is definitely located. But a very different state of things is likely to occur when the bowel at that point becomes progressively distended and inefficient, and when a chronic constipative tendency has been established. The anatomical relations are no longer normal, either as concerns the cæcum, or the meso-cæcum when it exists, or the ascending colon. The latter may be temporarily overloaded with fæcal masses, or it may take on a chronic paretic condition. Peristalsis is proportionately lost; in the chronic groups of cases the cæaum may never be emptied entirely. And what may we infer as a legitimate consequent from these conditions? "It is a fair inference," says Dr. Barker, "that the swarms of micro-organisms that successively work over these detained waste contents of the cæcum are more numerous here than in any other portion of the alimentary canal." It is a clinical fact that the disengaged gases—disengaged but not liberated from that angle in the canal—bring about a more and more relaxed and paretic muscular state. The author has seen this so often that he thoroughly believes in what may be called the paretic cæcum. This may occur in persons whose bowels are reported to be "regular," but constipation is the rule; there may be some degree of distention at the McBurney point, and also some malaise from an autointoxication of fæcal origin.

The next step implies that this paresis of the cæcum effaces the folds and valves that protect the appendix-orifice. The latter is made to gape and may then more readily admit of seeds, concretions, fragments of fæces and the like. With these, and even before them, there may enter the appendix those micro-organisms that infest the canal and its waste products. "And as foreign bodies of appreciable size are oftener absent than present in appendicitis"—and here we have perhaps the seed—thought of Dr. Barker's propositions—"it is quite probable that these microbes not only gain entrance into the appendix, but that they are *the real exciting cause* of the destructive inflammation.

As a merely suggestive addition the writer asks if the bacillus of Klebs-Loeffler may not be the organism that has brought about the present increased prevalence of appendix mischief. It devolves on some one or more of our bacteriologists to throw light on this hypothesis. It may also be questioned if recurrent appendicitis can be made to rhyme with this proposition; for, if the germs of Loeffler or any other pathogeny can thus become entrapped within the walls of the appendix, can their course be other than progressive and without remission—therefore without recurrence? Possibly not, since the microbes would seem to have their most favoring terms of propagation, with a source of supply in the cæcum unreduced and practically limitless.

The work of the microscope seems to be especially called for in this pathogenic field. We need it, in this class of the inquiry more especially, in order to determine whether the parent disease is cæcal or appendical. Dr. Barker's line of therapeutic suggestion based upon the idea of a paresis of the cæcum, permitting bacillar extension and consequent trouble, implies the use of intestinal disinfection and laxation. He states that salol, phenacetine and the mild chloride of mercury have helped him over some "rough spots in the road." During the last three months he has had three cases concerning which he believes that this line of medication has put him in the way of obtaining, in each case, a speedy and good recovery; two of his patients were young lads, the other was a man of fifty—they all three were original seizures.

In a recent meeting of the Clinical Society of London, Sir Dyce Duckworth spoke to the point of the nomenclature of right-groin trouble, and he averred that he did not subscribe to the dropping of the "typhlitis" and the supplanting thereof by "appendicitis," a word which might be American, but certainly is not English. He would undertake to say that this latter word will not appear in the next edition of the Nomenclature of Disease, now in course of compilation by the Royal College of Physicians, nor in the Transactions of the Society. He urged that there must be a great many cases of trouble in the right groin, not associated with an originally diseased state of the appendix, such as a local inflammation of the caput coli, "for which the best remedy was a purge." He had seen many cases of catarrh of the vermiform appendix probably caused by exposure to cold, and an easy step beyond that point will be the formation of concretion in that location.

When we reflect that the word "appendicitis" is only five years old, we can readily understand and almost approve that conservatism of our British friends that leads them to hold that word on a longer probation. But we will make this prediction that if the forthcoming Nomenclature does not contain the term, then the edition next to follow will admit it. The term has come to stay. And furthermore, we may expect other new terms, derived from the same root-meaning, to fit in with our growing knowledge regarding right-groin inflammation. For example, the word "appendectomy" has already been proposed in order to cover, with one word, the idea of a laparotomy performed for the relief of appendicitis.

Camphoid, a new Collodion.—The *American Druggist* refers to the above named substance as a possible substitute for collodion. It is a property of iodoform that it is soluble, one part in ten, in Rubini's solution of camphor—that is, equal parts by weight of camphor and absolute alcohol—and may be thus used as a topical application. This requires fixing on the part, to get the best results; this object is attained by the addition of pyroxylin, one part in forty of the iodoform and camphor solution. A complete solution can be made in these proportions. When applied to the skin with a brush, the fluid does not spread, but dries up in a few minutes and leaves an elastic opaque film that will not readily wash off. The excess of camphor volatilizes and masks the odor of the iodoform. The gun-cotton may be used with the simple camphor solution, in the strength above mentioned, and be made to serve as an eligible base for dermatic medicaments, such as resorcin, chrysarobin, ichthyol, iodine, carbolic acid or salicylic acid. Martindale, in the *Pharmaceutical Journal* for April 9, suggests that, if the camphor and pyroxylin solution shall prove acceptable to the profession, it may be named "camphoid..' In that event, the formula would read as follows: Camphor, 20 parts; absolute alcohol, 20 parts; pyroxylin, 1 part.

The Three Stages of the Medical Student's Life.—The late Dr. Henry Gawen Sutton, of London Hospital and College, was in the habit of dividing up medical student life into three stages, as follows: "First, he doesn't know; second, he thinks he knows, and then he doesn't know, but he stands on his feet like a man, and gives confidence to his patients."

The Citation by J. B. H., on page 145 of this current number, of the line from Pope is a movement in the right direction. It goes to show that, even as late as the time of that poet, the disagreements of dialecticians were more prominent in his mind, at least, than were the differences of medical men. But anterior to Pope there was an old latin saying—probably from the times of the schoolmen—containing the words *doctor*, in the sense of teacher, and *discipulus*, or student, in antithesis. This latin adage, and its side-lights, would help to rectify a blundering slur on medicine.

Dr. Chas. Warrington Earle has resigned the call to Rush Medical College, of which mention was made in our last issue.

ABSTRACTS.

Venomous Snakes of North America.—Dr. Barringer, of the University of Virginia, has given, in the last volume of *Transactions* of the Southern Surgical and Gynecological Association, his views regarding the dangerous serpents of the United States. The rattlesnake, the copperhead, and the water moccasin are sufficiently established in their reputations and have been often described; the first of these is sluggish, the second agile, and the third spiteful. The dangerous capabilities of the harlequin snake, the *elaps fulvius*, however, are less known. This beautiful little reptile, sometimes known as the coral snake or bead snake, is the only known representative of the cobra family in North America. It is found from Virginia to Texas. Its average length is not more than eighteen inches; in color it is blue-black, with brick-red and yellow bars along the caudal extremity. It is gentle and may at times submit to handling without biting. It has fangs, however, and Dr. Barringer has known of a fatal case, death following within twenty hours after its bite. The author estimates that ten per cent. of rattlesnake bites cause death; only one per cent. by the copperhead, and no deaths are known to him as having resulted from the bite of the moccasin. No bacteria have been found in the venom of snakes freshly taken, but a host of septic bacteria may exist in the saliva of these animals, left in the mouth from its food. These latter germs flourish to a greater or less extent in the buccal mucus, and in the case of the copperhead this mucus is so abundant that the name "cotton-mouth" is frequently applied to the snake. In about five per cent. of snake bites a chronic septicœmia is a result of the introduction of these septic germs of the salivary fluid.

BOOK REVIEWS.

A Treatise on Diseases of the Nose and its Accessory Cavities. By Greville MacDonald, M.D. Second Edition. London and New York: Macmillan & Co.

This little volume of less than four hundred octavo pages is dignified by the author with the title prefix of "A Treatise," which its size makes us resent, but if we measure the value of its contents by the character of its subject-matter, we are quite ready to say the title is well deserved.

The author further tells us the book is written particularly for general practitioners. In this he has hit the mark. Nasal affections are among the most common of maladies. Many are easily treated by the general practitioner, for the success of which he needs just such a guide as we find in Dr. MacDonald's book, which sells for the modest sum of $2.50. The illustrations are numerous and excellent.

Public Health Papers and Reports, Vol. XVII, presented at the nineteenth annual meeting of the American Public Health Association, Kansas City, October 20–23, 1991.

The annual volume of the American Public Health Association is before us, and as usual made up of a series of papers by eminent sanitarians, every one is of special value, the scanning of which makes us wish for space to add to its usefulness by a republication in the pages of The Journal.

The next meeting will be held in the City of Mexico, November 30, 1892.

Fourteenth Annual Report of the Board of Health of the State of Connecticut. Year ended November 30, 1891. Registration Report for 1890 of Births, Marriages, Deaths and Divorces. State Printers, Tuttle, Morehouse and Taylor: New Haven. 1892.

This volume contains 650 pages, of which 446 are devoted to the sanitary operations of the Board, under the supervision of Dr. C. A. Lindsley, Secretary, while the remaining pages contain the tables and comments of the Bureau of Vital Statistics.

The State appears, from the reports of the various districts, to have been comparatively free from typhoid fever, in epidemic form, as compared with some recent years. One of the papers of this Report, however, gives some important details respecting an outbreak of fever at a hotel of a popular summer resort. One of the features of the epidemic was the fact that none of the victims were taken down with the fever until they had returned to their homes. And thus it yields a curious instance of typhoid fever taking its origin in one place, from a given water-supply, and the patients separating to widely distant parts of the country during the incubation period, and becoming sick simultaneously or about the same time. The investigation was undertaken by Dr. Herbert E. Smith, of Yale Medical College, and he appears to have welded a strong chain of evidence incriminating drinking-water drawn from cistern supply. The locality infected was Money Island. one of a group of islands in Long Island Sound, much resorted to in the summer months, a nearly bare rock of six acres extent. The infecting case was the keeper of the billiard hall, whose symptoms were those of a "walking case." Of twenty-seven guests of the inn, twenty were traced to their subsequent abodes and were known to have had the fever. One patient only died. None of the employés of the inn appeared to have contracted the disease, they having a different well water for their supply; this water was far from being pure, but it did not receive the infection to which the guests' supply was peculiarly exposed.

Another paper has for its subject the prevalence and peculiar conditions observed as to tuberculosis in New Haven, during a period of fifteen years, prepared by Dr. L.

S. DeForrest. He made a special study of the recurrence of the disease in the same dwelling-houses during those years. He concludes that not a few domiciles of that city have become distinctly dangerous as places of residence, and require specific although not difficult measures to be put in force in order to overcome their infective characters. These measures relate chiefly to the prevention of dried sputum in the house, and to the adoption of ventilation regulations in the homes of the poorer class of people.

A considerable space is given to the reporting of studies that have been made, during the past two years, concerning the surface drinking-waters of the State. There have been sufficient results from these studies to show that a good annual appropriation should be at the disposal of the Board of Health for many years to come. States which, like Connecticut, double their manufacturing wealth every few years, must expect to expend liberally and steadily, for the protection of their citizens from river pollution. Communities too easily ignore the responsibilities that belong to every phase of material advancement. There is no kind of prosperity that can be enjoyed gratis and without commensurate obligation in official life. It commonly rests with medical officials, too, to have to make the fight on behalf of the citizens and their endangered sanitary rights. We close this notice by quoting a wise saying from the Secretary's report, as follows: "It is a trite saying that a spring cannot rise higher than its source; it is equally true that a spring cannot be purer than its source."

A New Pronouncing Dictionary of Medicine. By John M. Keating, M.D., Fellow College of Physicians of Philadelphia; Visiting Obstetrician to the Philadelphia Hospital, and Lecturer on Diseases of Women and Children; Gynecologist of St. Joseph's Hospital; Surgeon to the Maternity Hospital, etc.; Editor "Cyclopædia of Diseases of Children," and Henry Hamilton, author of "A New Translation of Virgil's Æneid into English Rhyme;" Co-author of "Saunder's Medical Lexicon," etc. Price, cloth, net $5.00; Sheep, $6.00 net.

A voluminous and exhaustive handbook of medical, surgical, and scientific terminology, containing concise explanations of the various terms used in medicine and the allied sciences, with phonetic pronunciation, accentuation, etymology, etc.

Most physicians will be pleased with the author's adoption of the anglicized pronunciation, adhering, as he does pretty closely to the general rules laid down in Worcester for the accentuation of English words.

The table of signs and abbreviations is the best we have seen. The table of suffixes and prefixes adds much to the usefulness of the work. While the systematic labor of the author has given us a very valuable dictionary, the publisher has done his part in issuing a book of handsome appearance, but of unnecessary size. The type is new, and attractive in style, but at least two sizes too large. The paper is of fine quality, but extra thick and heavy, the latter qualification being very undesirable in a dictionary. The size of page is convenient but with altogether too much margin for the print. All of which makes us think the publisher is ignorant of the purposes of the book.

A System of Practical Therapeutics, edited by Hobart Amory Hare, M.D., assisted by Walter Christie, M.D., Vol. iii.

This portly tome and last volume of this system of therapeutics follows quickly after its predecessors. The several sections are on Diseases of the Skin, of the Nervous System, Genito-urinary Apparatus, the Eye and Ear. All of which are followed by a complete index.

The chapters on skin diseases are by Drs. H. Radcliffe Crocker, W. A. Hardaway, J. Nevins Hyde and M. B. Hartzell. All of whom are recognized authorities in this specialty.

Among the authors on diseases of the nervous system, we find the names of Edward N. Brush, H. M. Bannister, B. Sachs, J. C. DaCosta, M. Allen Starr, Chas. K. Mills, Landon Carter Gray, Wharton Sinkler, C. E. Riggs, J. Ransohoff, T. D. Crothers and F. H. Dercum.

In like manner the other sections of the work are filled with chapters by prominent and well known specialists, whose professional standing places their literary work beyond the realm of criticism.

SELECTIONS.

Hereditary Transmission of Mutilations.—Dr. C. G. Lockwood, of New York, has recently published some interesting results of his experiments on the hereditary transmission of mutilations. White mice were selected on account of their rapid breeding, as they begin to breed every thirty days. He bred them in-and-in for ninety-six generations, destroying all the sickly and defective ones, and in this way obtained a larger and finer animal than the original pair. His experiments in breeding their tails off were done by selecting a pair and putting them in a cage by themselves and clipping the tails of all the young. When these were old enough to breed he selected a pair, and when they had young, clipped their tails. By continuing this breeding, in the seventh generation he got some young without tails, and finally got a perfect breed of tailless mice. By taking one with a tail and one without a tail, and alternating the sexes in each generation, he finally again got a breed of all-tail mice.—*N. Y. Med. Record.*

Prevention of Puerperal Sepsis.—The application of prophylaxis can have no more useful place than in the lying-in chamber. It is here that an ounce of prevention is worth many pounds of cure. It is doubtful whether puerperal sepsis can be cured in every instance of its invasion, but it is almost certion that it can be prevented in ninety-nine cases out of a hundred. The absorbing interest which is manifesting on this subject is apparent when medical societies in cities, towns and hamlets are everywhere discussing the question with a degree of earnestness, intelligence, and liberality that is as encouraging as it is instructive.

There can be no doubt that a great responsibility rests upon the obstetrician of to-day, greater than at any period in modern times. He must contest the ground with the abdominal surgeon for a record, and especially must he contest the field with the maternity physician for as good work in the mansion, the villa, the cottage and the tenement house. The family physician, who is likewise the obstetrician in the rural districts, must be able to show as good a record as his brother who practices in the courts and alleys of the populous cities, or as he who has the advantage of service in the lying-in hospitals. A few years ago the crowded maternity was considered about the worst place in which a woman could be confined. It was often necessary to close up such an institution when invaded with an "epidemic" of puerperal fever. Now such a thing as closing a maternity by reason of a large number of consecutive deaths from puerperal sepsis is unknown. In a thousand cases we hear of scarcely a death, and there is no such thing as an "epidemic" of puerperal fever.

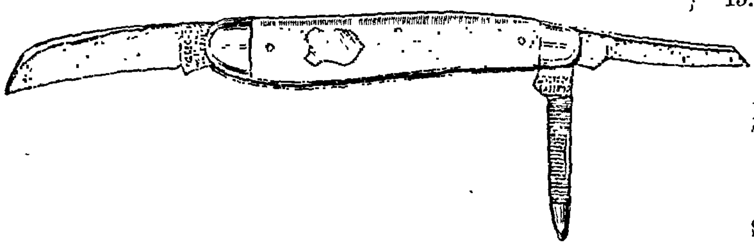
We have said that much responsibility rests upon the shoulders of the family physician in the rural districts, and he must look to it that his cases are properly prepared for confinement by clean hands that are versed in all that is meant by the term "asepsis." When the general practitioner can be made to enforce the simplest rules of asepsis that he perfectly well understands, but is careless about enforcing, we shall soon hear almost nothing of puerperal fever or of ophthalmia neonatorum. It is not competent to plead lack of time or inconvenience in carrying out those simple details of cleanliness which are the foundation of prophylaxis in the lying-in chamber, and which must be insisted upon where human life is at stake, or loss of vision in the new-born is so often threatened.

Quinquaud has confirmed Unna's statement as to the presence of a special microbe in soft chancre. It is a bacillus with rounded ends, and is generally arranged in chains. It is present in prodigious numbers in the lymphatics and intercellular spaces.—*Medical Review.*

A POCKET PLASTER-KNIFE.

BY JNO. RIDLON, M.D., CHICAGO.

At my suggestion J. Curley & Bro., 6 Warren St., New York, have constructed the knife shown in the illustration.



The large blade is a short pruning blade of extra thickness in the shank and thin at the point for use in cutting down plaster corsets and such splints as the surgeon may desire to preserve in perfect shape. The pen-blade is for use when it is desired to preserve the jacket or splint. Being entered obliquely layer by layer of the plaster bandage rises as it is cut through, all troublesome wedging of the knife is avoided, and the chances of wounding the patient are lessened. The third blade is a nail file with Curley's patent burnisher.

MISCELLANY.

Meeting of the American Electro-Therapeutic Association.—The next meeting of the American Electro-Therapeutic Association will be held this fall in New York City, at the Academy of Medicine, on October 4, 5, and 6. The President is Dr. William J. Morton of New York, Secretary, Dr. Horatio R. Bigelow, 1716 Chestnut St., Philadelphia. The local Committee of Arrangements are Drs. Robert Newman and A. H. Goelet of New York.

American Dermatological Association.—*Programme of* the Sixteenth Annual Meeting of the American Dermatological Association to be held at the Pequot House, New London, Conn., September 13, 14, and 15, 1892.

Papers:

1. Iodine and Carbolic Acid in the Treatment of Skin Diseases, by Dr. C. W. Cutler.
2. Additional Note on the Treatment of Erysipelas based upon a second series of fifty Cases, by Dr. C. W. Allen.
3. A Suggestion for Operative Procedure on erectile Nævi over Fontanelles, etc., by Dr. S. Sherwell.
4. How Should Dermatology be Taught? by Dr. G. H. Fox.
5. A Somewhat Unusual Case of Lupus Ulceration of the Nose, by Dr. H. W. Stelwagon.
6. Lupus Vulgaris following Exposure to Tuberculous Sputa, by Dr. W. T. Corlett.
7. Notes on the Treatment of Lupus Erythematosus, by Dr. J. Zeisler.

Discussion on Alopecia Areata:

1. Are there two forms of alopecia areata; one parasite and one neuropathic?
2. Is there sufficient evidence to prove the contagious nature of the disease?
3. Does arsenic or any other internal remedy influence the course of the disease?
4. What is the comparative value of carbolic acid, and of other topical remedies?
5. Will epilation of the margin of the patch prevent its spread?
6. What circumstances influence the prognosis of the disease?

8. Alopecia Prematura; its most Frequent Cause, by Dr. G. T. Elliot.
9. Cases of Favus Contagion from the Lower Animals, by Dr. S. Sherwell.
10. Some Observations on the Growth of Achorion Schoenleinii in America, by Dr. L. Heitzmann.
11. Morphœa Atrophica, by Dr. R. W. Taylor.
12. Psorospermosis, by Dr. M. B. Hartzell.
13. Report of a Case of Adenoma Sebaceum, with Microscopic Drawings, by Dr. J. A. Fordyce.
14. Concomitance and Sequence in Skin Eruptions, and the Influence of one Dermatosis upon another, by Dr. C. W. Allen.
15. The Cicatrices of Syphilis, by Dr. J. N. Hyde.
16. An unusual Case of Syphilis, by Dr. R. B. Morrison.
17. An exaggerated Case of Impetigo Contagiosa, by Dr. G. T. Elliot.
18. Notes on a Recent Visit to the Leper Hospital, Havana; Leprosy in Charleston, S. C., etc., by Dr. W. T. Corlett.
19. Notes on the Use of Thilanin, by Dr. G. H. Fox.

Southern Surgical and Gynæcological Association.—The annual session of the Association will be held in Louisville, Ky., on November 8, 9, and 10. Those proposing to assist in making the meeting a success by the contribution of papers should promptly notify the Secretary, Dr. W. E. B. Davis, of Rome, Ga., of the titles at their earliest convenience. To those desiring to nominate candidates for membership, blanks will be furnished on application. Dr. J. McF. Gaston, of Atlanta, Ga., is president, and is actively at work to make this session as great a success as any of its predecessors.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from July 16, 1892, to August 5, 1892.

Capt. Edwin F. Gardner, Asst. Surgeon U. S. A., is granted leave of absence for fifteen days.

Major C. E. Munn, Asst. Surgeon U. S. A., leave of absence granted for seven days, and extended thirteen days, is hereby further extended three days.

Major Alfred A. Woodhull, Surgeon, granted leave of absence for two months, to take effect on or about August 1, 1892.

P. A. Surgeon Henry B. Fitts, U. S. Navy, is assigned, temporarily, to the charge of the Army and Navy General Hospital, Hot Springs, Ark., to take effect during the absence therefrom of Surgeon Woodhull, the surgeon in charge. *By direction of the President.*

Major C. E. Munn, Surgeon U. S. A., leave of absence granted for seven days is hereby extended thirteen days.

Lieut.-Col. Charles R. Greenleaf, Asst. Medical Purveyor U. S. A., will proceed at the proper time to Montpelier, Vt., and visit the camp of the Vermont National Guard during the period of its encampment, commencing August 23, 1892. By direction of the Secretary of War.

Major J. K. Corson, Surgeon U. S. A., granted leave of absence for one month, to take effect on or about August 2, 1892, provided Capt. W. B. Banister, Asst. Surgeon U. S. A., shall have returned from leave of absence, with permission to apply for an extension of one month.

Capt. William O. Owens, Asst. Surgeon U. S. A., leave of absence extended fourteen days.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending August 13, 1892.

Surgeon P. A. Lovering, ordered to the Marine Rendezvous, Boston, Mass.

The Journal of the
American Medical Association

VOL. XIX. CHICAGO, AUGUST 20, 1892. No. 8.

ORIGINAL ARTICLES.

THE MANAGEMENT OF GANGRENOUS HERNIA, WITH REPORT OF A CASE.

Read in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892

BY JOSEPH RANSOHOFF, M.D.,
OF CINCINNATI, O.

(*Concluded from page 198.*)

When gangrene involves the entire knuckle strangulated the appearances are sufficiently characteristic. Chocolate or dark slate colored, denuded in patches of its peritoneum and in a collapsed condition, it fails to react to mechanical or chemical irritation. The odor is fetid before perforation has taken place. Where the strangulation has been very acute, as in the last case reported, the changes in and about the hernial sac need not be very marked. After the escape of a varying amount of turbid bloody fluid from the sac, the latter appears of a bright or dusky-red minus the glistening appearance of the normal serosa. When it is of older date one after another of the hernial coverings are involved in the inflammation. They are welded together, in turn to break down. A fecal abscess is the result. In the recent strangulation no difficulty is encountered in bringing the intestine into the wound after division of the ring. In that of four or five days, adhesions make this the most delicate part of the operation. It is here that the lesions most difficult to deal with are found, and which, with or without operation, are the most frequent death-causing factors.

The most serious and far-reaching changes in gangreneous hernia are often found in the afferent portion. They may be said to involve its calibre, its nutrition, its contents and the peritoneum singly or together. Although long recognized, the dangers inherent in this part of the intestine have recently been strongly brought forward by Beneke. Above the constriction there is always some dilatation with more or less paresis and congestion of the intestinal wall. It may be darker in color and œdematous from venous stasis. Possibly from the same cause its mucus lining secretes abnormally and as a result at times enormous accumulations of fluid are found. According to Mikulicz from one to three quarts. This forms an excellent culture medium for bacteria and in the process of putrescence toxines are formed, the absorption of which doubtless accounts for many deaths under the mask of acute sepsis from strangulated hernia before peritonitis has developed. The disintegration of this fluid gives rise to a fecal odor irrespective of the site of the constriction, and it is this fluid forced into the stomach and thence regurgitated that is so often mistaken for fecal vomit. (Mikulicz.) Furthermore the wall of a paretic and congested gut has no power to resist the pathogenic organisms which it encloses. Far above the constriction hæmorrhagic infiltrations, diphtheritic-like deposits on or ulceration of the mucus membrane may ensue. This is far more liable to such necrotic changes than the outer tunics and there is no way of knowing how far the process has extended. In one of Kocher's[15] cases the gangrene extended four inches and in one of Taendlers [16] six inches above the suture line. In a case not submitted to operation the diphtheritic deposits were found six feet above the constriction.

When death follows hernia, the symptoms of peritonitis are rarely absent. In the majority of cases, even of gangrene, there is no perforation within the the abdomen, and the course of the peritoneal infection must have been through the macroscopically intact gut. That it may occur where the gut does not enter into the hernia has already been seen (Case 1). It has long been known through Nepven's[17] investigations that the fluid transudate in a hernial sac is rich in pyogenic organisms before gangrene has developed. Boenveken[18] has recently shown that the bacteria readily pass through the wall of the paretic bowel and produce peritoneal infection. On microscopic sections he was enabled to trace their progress through the intestinal wall. From these metastatic infection in remote organs may ensue. The process is like that seen in other morbid conditions of the intestine; notably in typhoid fever and appendicitis, where peritonitis develops without actual perforation.

Equally important with the local, is the general condition of the subject of a strangulated hernia in determining the plan of procedure. When delay has brought the patient to the verge of collapse, when even the shock from prolonged anæsthesia cannot be ventured, that must be done which most readily gives relief to the strangulation. It may be the opening of a fecal abscess, the division of the stricture, or the rapid fixation of the gut in the wound. Whatever the procedure adopted in the condition indicated, the result will probably be the same—death within a few hours or days.

In most cases, however, the condition is less deplorable, and evidently tolerant of a somewhat prolonged operation. It is in this class that choice must be made between the establishment of an artificial anus and resection of the bowel, with immediate suture of the divided ends.

Unfortunately, authorities are not to be relied on, for they are divided. In England, Baker, MacCormac, Banks and Treves decidedly oppose the greater operation of resection. In this country the same opinions have been held, unless they have been recently influenced by the reports of successful cases of excision by McCosh,[19] Richardson,[20] Dawborn[21] and others. In Germany, Kocher's and Czerny's first successes were followed by many failures, which frustrated the natural desire of surgeons to make primary excision the normal procedure in gangrenous hernia. Finally, Reichel's[22] critical review of the statistics in 1883 made it appear that the preferable primary operation was enterostomy, to be followed by a second operation for the closure of the preternatural opening. From the very first Kocher has remained steadfast to the ideal operation, and in Mickulicz he has recently found a most able supporter.

The advantages and disadvantages of the two procedures are almost apparent. If primary resection is successful, the patient is well in from four to six weeks. If an artificial anus is established, a second operation of very serious nature must follow. The artificial orifice is as large as the bowel, and the mucous membrane is prone to prolapse. Such an opening never closes spontaneously.

While in a considerable number of cases the enterotome of Dupuytren might be successfully applied with the low mortality of 5 per cent. (Korte),[23] it will fail in many cases, and be absolutely inapplicable in others. Again, according to Dupuytren, it should not be used until two or three months after the primary operation. It is during this interval that the very greatest danger from the artificial anus is encountered, that from progressive inanition. Recently Poulsen[24] has used it twelve and even nine days after the first operation.

It has not yet been established how much of the intestinal canal is essential to the maintenance of nutrition, but where the fistula is above the mid part of the ilium, rapid emaciation and death follow before any secondary procedure for closing it can be practiced. McCosh does not overrate the argument of statistics in the statement that the death-rate of all cases in which an artificial anus is made, including the operations for its relief, is 50 per cent. The danger from secondary resection and enterorrhaphy is very considerable. Haenel mentions 43 cases, with 16 deaths and 2 failures.

To be successful the artificial anus must be established in healthy bowel, else the dangers inherent in the afferent portion will not be removed, nor will a free outflow from the intestine be secured. The only advantages, therefore, which can be claimed for this method, are the rapidity with which it can be performed and the slight technical skill required in its performance. A further advantage is supposed to exist in the lesser danger connected with this as compared with the major procedure of immediate resection.

There is hardly a subject in surgery concerning which statistics are so much at variance as are those relating to gangrenous hernia. According to Korte, of 111 cases treated by enterostomy, 11 ended fatally. Herman (quoted by Haenel) mentions 83 cases, with 7 deaths. On the other hand, Weil[25] reports 15 cases, with 13 deaths. Benno Schmidt places the mortality at 85.5 per cent. for the formation of an artificial anus, as against 71.1 per cent. for primary resection.

F. A. Southern, surgeon to the Manchester Royal Infirmary, recently reports 85 cases of herniotomy, with 9 cases of gangrene. All of the latter died. In 6 an artificial anus was made; in 5 primary excision

If statistics are of any value in solving the relative merits of enterostomy and primary excision, it is evident that the reports of scattered cases are far less weighty than such from a few and skilled operators, and from hospital records where nothing is concealed. Such a tabulation has recently been made by Mickulicz[26] from seven large clinics of Germany and Switzerland. Of 168 cases of gangrenous hernia, 109 died. Of 94 in which an artificial anus was made, 72 died; mortality 76.6 per cent. Of 68 primary excisions, 32, or 47.1 per cent., died. Of 6 intermediary resections, 5 died. It would appear from this that the mortality of primary excision is very much less than that of the lesser operation. But this can be accounted for by the certainty that the latter was often used as a last measure in conditions approaching collapse and therefore precluding the major operation.

The advantages of the primary operation are patent. Its disadvantages are in the time required for its performance and in the danger of peritonitis from imperfect technique. In a measure both can be overcome. The first of these is probably grossly exaggerated. With separation of the mesentery as indicated in the fourth case, and its closure by suture, to be followed by the continuous Lembert suture or by lateral anastomosis, not more than half an hour at most should be required for the enterorrhaphy. Complicated clamps, a separate row of stitches for mucous and serous tunics, interrupted sutures, unnecessarily waste time. Where the continuous suture is used and appears weak at points, a few supplementary stitches can easily be taken. Suturing the mesentery brings the intestinal ends naturally together, and gives assurance that the most treacherous part of the suture, that near the mesentery, can be properly applied. The second danger is from injudicious selection of the lines for suture. As elsewhere in gangrenous processes, the danger lies rather in removing too little than too much. If Kocher excised five and Koberle six feet of intestine, a few inches more or less cannot be important. In acute cases where the calibre of the gut has not been long occluded, and kerporostasis is little if at all developed, an inch or two on each side of the constriction groove will probably bring the suture line in healthy tissue. Where the mesentery has not been included in the strangulation the same favorable conditions may be expected. Where, however, much dilatation of the afferent gut exists, its thorough evacuation should precede the enterorrhaphy. After hernia as after laparotomy for obstruction, it is fatal to return a distended gut to the abdomen. The second danger, that of septic infection of the peritoneum, can in a large measure be reduced by thorough irrigation of the sac before suturing; by careful handling of the gangrenous gut without the wound, meanwhile protecting the peritoneum by gauze packing. Finally, the sutured intestine should be left just within the abdominal cavity and a radical cure should not be attempted. Mickulicz, whose success surpasses that of any other operator, 21 cases with 14 recoveries, insists on the open treatment of these cases. Should fecal extravasation ensue from defective suture or other cause, it would naturally turn toward the wound, whereby the danger of general peritonitis would be largely averted. For from two to five days after the operation the sutured intestine remains where it is placed within the abdomen, and after that length of time the development of peritonitis is not probable. To hasten the process of wound repair, deep and superficial sutures might be drawn through the wound margins and kept over the gauze packing, to be tight-ened without anæsthesia after the danger line has been passed.

Between the extreme measures considered, others looking towards a compromise have recently been brought forward by a number of surgeons. Among these are the intermediary excision and suture of Riedel.[27] The artificial anus is established in the usual way. After twenty-four or forty-eight hours the edges of the intestines are vivified and united by suture.

In 1882 Bourlly[28] suggested excision and suture, the latter being purposely made imperfect at one point to guide fecal extravasation. To avert the danger from imperfect suture, Hahn[29] follows the kelotomy with a median laparotomy. Through this wound he brings the divided ends of the bowel, thoroughly protecting the abdomen against infection by packing them in gauze. When the suture is completed, the closed knuckle is kept in the wound on gauze splints until union is assured. The competency of the suture is certain after twenty-four hours, when the bowel is returned to the abdomen and the external wound closed. It is difficult to understand why the same procedure could not be carried out in the inguinal herniotomy wound. Nevertheless Hahn has had two successes with it, and in a third reported by Kutschera[30] the result was equally satisfactory.

To overcome the danger of death from inanition, Helferich[31] has recently combined enterostomy with an intestinal anastomosis above the constriction furrows. By this method two courses are open to the intestinal circulation, and the closure of the artificial anus is greatly facilitated. The operation was done in two cases, one of which was successful, the fecal fistula closing spontaneously.

There is yet another class of cases in which the condition of the bowel is such that whereas gangrene is not yet present, it might through subsequent necrosis cause death, if returned to the abdomen. Such a knuckle is a menace. Who has not seen it; especially if operating by light both artificial and bad? Bowel that is not at all doubtful in appearance will at times repay the trust placed in it by a perforation. Among 96 deaths after herniotomy, it was in 26 cases the result of returning intestine to the abdomen which subsequently perforated. In Hagedorn's clinic three deaths out of fifteen resulted in the same way. To return doubtful intestine is unnecessarily jeopardizing life. To treat such intestine as radically as bowel already gangrenous, is an extreme measure not to be advocated. Fortunately, the intestine can be retained in the wound for a number of days by gauze packing or by sutures. When its viability has been established it is an easy matter to return it to the abdomen. Graefe[32] recently reported a successful case in which the intestine was so retained for five days before replacing it. Should the dread of adhesions be feared, the intestine might be retained just within the abdomen by fixation sutures or by gauze. In the event of gangrene the fecal extravasation would course towards the external wound.

When, in 1880, Czerny reported his first case of primary excision for gangrene, he believed that the operation would not displace the older operation of enterostomy. Although the last four years have brought forward success after success from primary resection, the dictum of Czerny still holds good. Each operation has its proper field. The boundary lines are becoming more clearly defined. Nevertheless, it must always remain for the judgment and tact of the surgeon, as individual cases arise, to determine the proper procedure to be adopted. In operative surgery as elsewhere, the ideal should be sought. This would make primary excision, the normal procedure in gangrenous hernia, and only cogent reasons should cause the operator to refrain from striving for the ideal.

Dr. Marcy, of Boston, opened the discussion by complimenting Dr. Ransohoff. Sometimes he thought we had too many operators, or rather too many attempting to operate who had not had the proper training. It is part of every physician's duty to know how to operate on a strangulated hernia. The inguinal hernia in the male is the most difficult class of hernia to cure. We have an opening that must necessarily be patent in every healthy man, and the wonder is that every male has not a hernia. Three centuries ago these herniæ were cured by sacrificing the testicle. Dr. Marcy described the different methods of radical cure, and emphasized the advantage of bringing the skin together by means of buried sutures so that not a vestige of a stitch is in sight. This stitch is very simple, but he had had great difficulty in teaching it to his professional brethren. By its use we avoid drainage and are able to seal the wound with iodoform gauze, and we may rest assured that if the wound is aseptic it will remain so, and patients are often up on the second or third day. The youngest child he had operated on by the sealing method was two months old, and of twenty operations 90 per cent. have remained cured. In femoral hernia most cases are cured by opening, stuffing and allowing to granulate. He had never operated on a case that was not cured. The only danger is the puncturing of the femoral vein, but that is the first thing that should be looked for. In umbilical hernia the whole sac should be removed, the danger then being from the thin walls in the neighborhood, which can, however, be reinforced. The chief points in the treatment of hernia are: aseptic or antiseptic surgery, the use of antiseptic sutures that can be left buried, and the wound so treated that it can remain closed and no dressing be employed.

A FEW POINTS ON THE MANAGEMENT OF STRANGULATED HERNIA.

BY W. B. DE GARMO, M.D.,
PROFESSOR OF SPECIAL SURGERY (HERNIA) IN N. Y. POST-GRADUATE MEDICAL SCHOOL AND HOSPITAL.

The death rate from strangulated hernia throughout the land, has not diminished as it should have done in the face of modern surgery. Notwithstanding the mass of literature that has been devoted to this subject, and the fact that its importance has been fully recognized, from the earliest times to the present, strangulated hernia remains to-day as in years gone by, the dread of the average practitioner of medicine. Physicians who ordinarily act promptly and in the best interest of their patient, hesitate over strangulated hernia, trying first one thing, and then another, actually "frittering" away valuable time, and thereby sacrificing life.

This hesitation, and fear, not doing the right thing at the right time, perhaps has its origin, first, in the dread of former years, of touching any thing relating to the peritoneal cavity, and second, to the manner in which most of us were taught the anatomy of the parts.

It is not with the hope of presenting anything particularly new that this paper is brought before the surgical Section of the American Medical Association, but it is to emphasize in as concise a manner as possible, a few cardinal points in the management of strangulated hernia, and to enlist the aid of this Section in breaking up some false ideas retained by physicians as to their course of action with their cases.

With the physician who first sees the case rests the burden of responsibility, and if incompetent to carry out means of relief himself, he should realize that in not promptly placing the case in the hands of a man who can apply them, he is almost criminally indifferent to the welfare and safety of the patient.

When we are called to a patient who has abdominal pain, vomiting and distress, and who has a tumor in one of the regions subject to hernia, with perhaps a history of a swelling formerly reducible, but now not so, there is no difficulty in making a diagnosis of strangulated hernia. We do not always have so clear a picture as this. Local pain, even pain in any part of the abdomen is sometimes entirely wanting.

Three years since I was called in consultation and to operate on a young man attacked five days previously, where four different physicians had been in attendance, and only one had suggested strangulated hernia, because abdominal pain had been absent. When I operated, general peritonitis was well established as the result of a knuckle of gut constricted at the external ring. Here was a young man with a history of hernia, suddenly attacked by extreme depression amounting almost to collapse, with vomiting and with an irreducible swelling in the scrotum, and still his life was sacrificed while the doctors wrangled over the question whether it was an inflamed piece of omentum, an orchitis, or a strangulated hernia.

Pain at the point of constriction is in many cases absent, but general abdominal distress or "colicky" pains in the region of the navel less commonly so—this, general distress and the anxious expression of the face should in themselves be sufficient to tell of the serious character of the case and the need of prompt action, especially when we have the added evidence of a hard and irreducible tumor.

All of these symptoms are masked by the hypodermic use of morphia which is usually the first remedy applied by the attending physician—many a sufferer from strangulation being sacrificed by the use of the hypodermic syringe.

I cannot emphazize this danger to strongly. If opiates are used, do not allow them to deceive you into inactivity. The pathological changes are rapidly going forward. Your patient is on an express train whose destination is death, and it is traveling with frightful rapidity.

I look upon shock or collapse as one of the most important symptoms which we ever see in strangulated hernia, and when present, should cause us to act with decision, and promptitude. Many cases of death have been recorded as due to the shock consequent upon operation, which in fact were due to the disease and to the delay in relieving it. This only serves as a lesson to us that we must not allow these patients time to fall into this condition of profound relapse.

Intestinal obstruction has of course an important bearing upon some cases of a mild type, but this does not justify the delay which is in many instances caused by trying to ascertain by the aid of enema, or cathartics, whether such a state of affairs really does exist.

NON-SURGICAL TREATMENT.

In considering non-surgical measures for the relief of the affection under discussion, I will first make a brief review of its medical treatment. Those who follow the literature of the subject for the first time, will be surprised both at the number of remedies, and at the confidence with which they are put forward. One would almost think that the surgical treatment of this trouble would no longer be necessary, did we not observe at the same time that the death rate keeps as high as ever. There is no doubt in my own mind that the medical treatment of these cases does far more harm than good, and that could all drugs be abandoned and the subject treated as a purely surgical one, many lives would thereby be saved. Because a case that has been injected by atropia, morphia or hyoscyamine has afterwards been reduced, this is no evidence that it was due to the effect of the drug.

Those who operate upon these cases can produce an equal, or larger number who, through having tried these vaunted remedies have lost the valuable time that meant death to the patient.

Muscular spasm as a factor in the production of strangulated hernia, and as something that must be overcome in its treatment, no longer holds a prominent place in the surgical mind, and the sooner it is banished from the minds of *medical* men, the better it will be for those who suffer.

The sooner the entire profession realize that it is as purely a mechanical difficulty, as is a piece of beefsteak lodged in the throat of a choking man, the sooner will prompt relief be afforded those who are afflicted. Delicate and vascular parts are forced out through an opening composed of hard, non-elastic fibrous tissue. At first the constriction may be only sufficient to retard the return of venous blood. The resistance of the arteries being greater, the blood is still pumped freely into the parts, while its return by the veins is obstructed. Congestion results, and the constriction tightens until all circulation is shut off, and death of the part results. With this state of affairs existing, why give hyoscyamus atropia, chloral hydrat., or even opiates, except to alleviate the sufferings of the patient while making preparations to do something more rational? Why not do the only right thing at once? that is, cut the constricting band.

EXTERNAL APPLICATIONS.

I shall not stop to discuss the many external applications that have been credited with great power in reducing strangulated hernia. Heat, cold, poultices, croton oil and other liniments, have all had their advocates, and to faith in each, has some life been sacrificed. Evidence is strong, however, in favor of the local application of sulphuric ether.—Finkelstein claims to have reduced fifty-four out of fifty-eight cases by this means alone. The hips are elevated, the parts exposed to the air and well anointed with sweet oil, then about a tablespoonful of ether is poured over the tumor every ten or fifteen minutes.

It is supposed that the intense cold produced by rapid evaporation, acts not only upon the engorged blood-vessels, reducing their size, but upon the bowel itself. I believe this to be safer and more efficient than taxis in the hands of the inexperienced. I should feel regarding this, as with the use of ice, that it should only be used in the earlier stages, before the vitality of the part has been impaired, and that it should not be continued over a great period of time.

TAXIS.

Dunglison gives the definition of this word as "the operation of reducing a hernial tumor by the continued pressure of the hand"—but I have found that the interpretation of the term by the profession at large, may be anything from the most gentle manipulation, to the mauling and pommeling of the tumor, or even of putting the patient on the floor and jumping on him, as had actually happened to a man who came under my care a few years ago.

In the manipulations known by the term "taxis" we have a power for good or a power for great evil, and I regret to say that as ordinarily used, the one almost counterbalances the other.

None but the most gentle manipulations should ever be used upon a strangulated gut, or even an incarcerated piece of omentum. This should be done mostly before the patient is etherized; the temptation to resort to "brute force" is too great when the patient is insensible to pain. I desire to give here a method for reducing hernia, that has been followed by me for many years. I claim no special originality, but do claim and know that it is not generally used.

Try at the outset to assure your patient that you are not going to add to his torture, and confirm this in his mind by handling the tumor with the greatest gentleness. By this you will secure his coöperation instead of unconscious resistance. Work the fingers of one hand around the neck of the tumor where it issues from the abdomen, holding its bulk in the palm of the hand if possible, and instead of trying to push this tumor back into the abdomen, *try to draw it further down*. Now with the other hand grasp the canal and its contents (if inguinal hernia), gently but firmly between the thumb and fingers, and while making *traction and compression* with the hand that is holding the tumor, manipulate the canal with a "kneading" motion. This can all be done without adding to the patient's pain to any extent, and it will succeed when ruder handling fails.

When you push upward upon a strangulated hernia, usually you carry it up over the edge of the ring upon the abdominal wall, and accomplish nothing more. In the method suggested, by *traction* you lengthen out the mass that is blockading the canal, favoring the effect which you afterwards produce by *compression*, *i. e.*, the partial emptying of engorged blood-vessels, and the displacement of imprisoned gases and fluids. This is further aided by the action of the fingers upon the canal, which tend to work the bowel free at the point of constriction.

This method applies with slight modification to any form of hernia with which we may meet. In enormous inguinal hernia, the pure rubber bandage may be called to our aid in making compression.

In femoral hernia we have a very short canal to act upon, and I have for this reason modified my manipulations in the following particulars:

The hand for *traction* and *compression* is used as before described, the tumor being drawn in a line at right angles with or directly away from the leg. With the fingers of the other hand, the neck of the tumor is "kneaded," and from time to time the abdominal wall immediately above the hernial opening is gently but firmly pressed deeply into the pelvic cavity, by the ends of the fingers carried just over the brim of the pubes.

This pressure deep into the pelvic cavity, displaces the viscera in the immediate vicinity of the internal hernial opening, and doubtless causes some traction upon the bowel from within.

I can recommend these methods of reducing hernia, with every confidence that those who try them, will find them more satisfactory than the usual way of applying taxis.

ANÆSTHETICS.

I shall mention only one more article under the head of non-surgical treatment, and that is the use of anæsthetics. purely as a means of aiding in the reduction of hernia. Here again we are using a two-edged sword; I have not hesitated to place myself squarely on record, as having no faith in the causative action of muscular spasm, and this means that ether merely allows us to use a force, that we would not dare use during the consciousness of the patient. One point in its favor I am willing to admit, it does away with the unintentional resistance on the part of the patient. I believe that an anæsthetic should always be used, but never by the man who is not prepared to cut down and sever the constricting band, before his patient comes from under its influence, in case he fails to replace the protruding parts, by moderate manipulation.

ASPIRATION.

Aspiration is on the line between the medical and surgical treatment of strangulated hernia. I believe that it is more frequently resorted to by the physician than by the surgeon. It is one of those vain hopes resorted to in order to avoid an operation, and one of the means that puts the patient in greater danger if not successful. The puncture of the bowel by the smallest needle when its vitality is already at the lowest ebb, furnishes a very favorable spot for the beginning of necrotic change, and notwithstanding the fact that they belong to a class of cases not fully published, there are enough on record to show that perforation is more likely to occur at just this point, than any other.

In a few instances where the hernia is incarcerated by its enormous size, rather than strangulated by a constricting band at its neck, it may by affording escape to the imprisoned gas, break up the blockade.

It is by no means an innocent measure to be indiscriminately applied.

WHEN TO OPERATE.

In former years there was some question, as to just when it was justifiable to operate, that is, just how far you were to allow your patient to go towards "death's door" before giving him relief. I regret to say that there are still a fair number of physicians who do not feel any alarm for their patients until fæcal vomiting begins, and believe that it is then quite time enough to talk of surgical measures. They fondly imagine that they are acting in the patient's interests by trying everything else, before the knife.

Then again there are a large number too timid to operate themselves, and not conveniently situated to call a surgeon. To these two causes many lives are sacrificed every year.

I look upon delay as by far the most dangerous feature of the case. In thirty-one cases of strangulated hernia in private practice I have lost three cases, and I am sure that two of those might easily have been saved by an early operation.

This good record is due to two causes—First that I have seen the cases early, and second that I have never left my patient until the hernia was reduced.

OPERATION FOR RELIEF.

Few operations are easier to perform than those done upon a recent case of strangulated hernia, before pathological changes have taken place, and few are more complicated after long delay.

The point of constriction in inguinal hernia, in a large majority of cases, is at or near the external ring, and in femoral it is rarely found deeper than Gimbernats ligament. In reaching these points only the most insignificant vessels are divided. The question of opening the hernial sac should no longer be under debate by those doing aseptic surgery.

Except in the smaller herniæ, recently strangulated, safety is on the side of examining the contents of the sac, and knowing by actual inspection that they are in a fit condition to return to the abdominal cavity.

We cannot without seeing, estimate the amount of damage that may be done to a loop of intestine, even in a very few hours. In femoral hernia, I have seen the gut, black, after only five hours' strangulation, so complete had been the arrest of circulation.

Then again within the sac we may have a piece of omentum which has long been outside of the abdomen, and so changed in character as to make its removal safer, than would be its return within the peritoneal cavity. Such hardened masses of omentum sometimes give rise to peritonitis. More than this, they are a very strong predisposing cause of the recurrence of the hernia.

Amputation of the omentum has long added very seriously to the mortality resulting from these operations, first, from secondary hæmorrhage, and second from sepsis. The common method of surrounding a large piece of this fatty tissue with strong cat gut, and then tying, cutting off, and reducing the stump to the abdomen, is dangerous in the extreme. Rapid absorption takes place, the ligature is loosened, and bleeding into the abdominal cavity results. Nothing short of laparotomy will save the patient.

For several years it has been my habit to spread these omental masses out on the abdomen and tie each vessel separately with small *aseptic silk*. I have placed as many as eighteen silk ligatures upon the omental stump. This method has the double advantage of ensuring safety against hæmorrhage, and also of allowing the omentum to spread out in a natural manner in the interior of the abdomen, instead of being held in one mass, as a convenient wedge to redilate the canal at later date. I sterilize my silk by boiling for twenty minutes in a carbolic solution, and it is then kept in alcohol.

The second risk—sepsis, is no longer a very great one with careful operators.

COMPLICATIONS.

Among the complications met with, none are more frequent than adhesions. These are mostly between protruding omentum and the sides of the sac, and are easily broken down. If, however, they are between the bowel and the sac, great care is sometimes required to separate them. It is far better to cut out that portion of the sac adherent to the gut, and reduce it in this way, than to run any risk of tearing the intestinal coat. Before returning the intestine it should be carefully inspected to see that it is not twisted upon itself, or that its surfaces are not adherent. Treves has shown that those who have suffered from strangulated hernia, are more liable to intestinal obstruction subsequently than other persons, on account of these adhesions lengthening out into bands that entangle the intestine. After reducing the bowel, it is well to introduce the finger and sweep it around the interior of the abdomen, to assure yourself that no adhesions exist in the vicinity of the hernial opening.

It is no uncommon thing, even in cases of short duration, to see the bowel of a dark chocolate color, in which cases, after the stricture is cut, the bowel should be kept outside of the abdomen and hot cloths wrung out of sterilized water applied, until a change towards its normal color is observed.

The use of any form of antiseptic solution upon the damaged bowel is strongly advised against, however. Small perforations may be surrounded by a circular stitch and closed. It is true that this narrows the lumen of the bowel, but a considerable narrowing is safer for the patient than resection. Even when there is sloughing demanding resection, it is believed that an artificial anus should be established until the patient has sufficiently recovered to warrant its closure by a secondary operation.

When in doubt what to do with the bowel the safer plan is to leave it outside of the abdomen, if necessary several days. If great shock exist at the time of the operation, or if general peritonitis is established, it is believed to be good practice to flush the abdominal cavity with sterilized hot water, water as hot as can be borne by the hand or even hotter.

OPERATION FOR CURE.

Having relieved the patient of strangulation, it should be our next consideration to protect him, as far as lies in our power, from a recurrence of the hernia. It is true now, as in all times past, that we have no method of cure for hernia that will not fail in a large number of cases. This is due to the fact that the same inherent defect exists in the structure of the abdominal wall, that acted as the predisposing cause of the original hernia. In many instances we cannot overcome this.

Fortunately we can now resort with impunity, to methods of restoring the parts to their normal condition, that were in former years very hazardous to the patient. This fact is leading to a larger percentage of cures and a greatly reduced mortality rate. There are very few instances when the operation for radical cure cannot follow that for the relief of strangulated hernia, without increased danger to the patient.

It is not within the scope and intent of this paper, to consider the various operations at present in use, and I will only say that during the past four years, I have used the operation of Baker, of London, with great satisfaction. This, briefly, consists of cutting off the sac as near the internal ring as possible and then stitching up the canal with heavy braided silk. Union by first intention is secured in almost every instance, leaving the deep silk sutures permanently in the canal. Since I have sterilized and prepared my own silk, I have no trouble about the stitches coming out.

The old routine of giving an opiate to keep the bowels quiet after operations for strangulated hernia is believed to be bad practice. Opiates are seldom called for to relieve pain, and should never be given for other reasons.

It is not an uncommon occurrence, that the loop of bowel which has been subjected to constriction, is in a state of temporary paralysis, when it is reduced to the abdominal cavity. Fæces collect at this point, and not only increase the danger of perforation, but if they become hardened may cause intestinal obstruction.

It is believed that the early administration of a mild saline cathartic, not only tends to prevent accidents of this character, but that it relieves the congestion of the bowel more promptly, than if left unaided.

In closing this brief, and necessarily incomplete consideration of a very extensive subject, if I have not shown my belief in the following propositions, then surely I have fallen far short of my desire.

1. That the death rate from strangulated hernia, is unnecessarily excessive.
2. That medicines, and external applications are dangerous, in that their use *often results in delay*, allowing destructive changes to take place.
3. That the operation for strangulated hernia, *if done early*, is neither a difficult nor a dangerous one, and affords immediate relief, from one of the most distressing and alarming accidents to which mankind is liable.

THE TREATMENT OF COMPOUND FRACTURES.

Read in the Section of Surgery and Anatomy at the forty-third Annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY W. H. MYERS, M.D.,
OF FORT WAYNE, IND.

The injuries of bone are classified as: simple fracture, compound fracture, complicated fracture.

What are the indications when called to treat a case of compound fracture?

To arrest the hæmorrhage, as far as possible; to render the wound aseptic, and to prepare to set the fracture.

The second indication: to keep the bones in normal position. The third indication: to conduct the case so as to prevent putrefaction, and to remedy septic infection when it has occurred.

I suppose we all admit the cause of putrefaction to be, the presence of microörganisms which enter the wound from without, and that the putrefactive fermentation of the discharges leads directly to septic infection; hence, any essential part of the treatment of wounds must be to prevent the entrance of these organisms.

To conduct a case so as to prevent the changes referred to we must ever bear in mind that germs are living.

All living things require certain conditions for their growth and development, vitality their poison. non-vitality their food.

We interfere with their growth and development by the use of antiseptics, a successful interference will give us an aseptic wound. The methods of interference may be stated as follows:

1. By removing the germs before they have had time to do harm, by washing out the wound.
2. By removing the soil in which they grow, by free drainage.
3. By rendering the soil inert; this may be done by constitutional treatment, by general and local rest, and by keeping the patient in as perfect health as possible, thus increasing the vitality of the tissues.
4. By preventing the deposit of the germs; this may be done by absolute cleanliness of the hands, instruments, ligatures, and by irrigation.

In support of these statements I shall quote McNamara, who uses the following languge: "I believe that with ordinary care we can prevent putrefaction and suppuration from taking place in cases of compound fracture by Mr. Lister's system of dressing." Also a quotation from Dr. David W. Cheever, of Boston: "The majority of compound fractures now are made aseptic and continue so, healing without amputations, formerly so common."

I now offer in support of the foregoing statements the following statistics:

Mortality of compound fractures during the pre-Listerian period.

Baum in Gottingen lost	38	per cent.
Billroth in Zurich lost	38.7	"
Billroth in Breslau lost	40.5	"
Billroth in Halle lost	40.6	"
Billroth in Bown lost	41.8	"

Under the Listerian treatment Professor Volkmann has 75 cases of compound fracture without a death.

Lister, Volkmann, McEurn, Bardenhuer and MacConnac report 530 affected with 1,072 compound fractures, and of these only three died. In discussing the treatment of compound fractures I shall only refer to immobility of the use of plaster paris, bone-grafting or transplanation with a case, and the question of amputation.

John Hunter said: "The first great requisite for the restoration of injured parts is rest." Complete rest, absolute repose. With a clear apprehension of these great principles, and a minimum of subsequent interference after *immediate* reduction, a good result will ensue. I have for more than ten years treated compound fractures upon the same principle as I do simple fractures if called early to see the case, and if the blood supply be not so largely interfered with as to cause gangrene. After thoroughly cleansing the entire limb with soap and water, and afterwards using a five per cent. solution of carbolic acid, for the same purpose (anæsthesia with ether), I close up the wound with protective, seldom using sutures, dusting the part with iodoform, also the adjacent skin; I then apply four or five thicknesses of bichloridized gauze and a layer of carbolized cotton, and complete the dressing by plaster paris bandages to give the needful support to the limb. These are applied spirally until every part of the limb and wound are covered by four or five thicknesses. Drainage I do not employ. If the fracture is below the knee I elevate the foot. I allow this dressing to remain fourteen days or even longer, unless thermometric indications present themselves for its removal. I would only then remove the dressing because of the subsidence of the swelling. The advantage of the dressing is, that the bandage applied in such a soft and pliant state as to accurately adapt itself to the limb affords a firm and even support when the plaster hardens. We thus secure perfectly immobility, muscular spasm is prevented, and with it absence of pain.

Infrequent dressing is a corollary of that fundamental principle of absolute rest during the healing process. This principle is not new, for Bellaste, in 1707 said: "I only dress a wound *infrequently*, convinced that we must give nature leisure to act in re-establishing wounded parts in their former state." The elder Larrey shows how far he carried the principle of immobility, and how little he cared to examine and dress wounds in soft parts by his treatment in the following case: "This soldier whose arm I amputated at the shoulder joint, during the terrible battle of Moscow, in 1812, at my request set out immediately on his journey homewards, without ever having the stump dressed, in accordance with the assurance that I had given him at his departure that he would not need it."

I assert the ideal wound dressing in a case of compound fracture to be that which affords perfect rest, *absence of tension with antiseptic protection.* Now contrast a simple with a compound fracture. To the question what is a fracture, Agnew replies: "It is defined to be a solution of continuity in the fibres of a bone." I answer, it is much more than this. Vessels are ruptured, periosteum torn, the sharp and irregular fragments wound the overlying tissues, blood is extravasated, the soft parts contused, and yet, so long as the skin is unbroken, no serious consequences will follow. The simple fracture, so called, if properly adjusted, unites easily and quickly without pain or fever. Why does this not occur in a compound fracture? Why have we fever, pain and extensive suppuration in one and not in the other? It is now proved that these consequences depend upon putrefaction of the wound secretions, and that the putrefaction itself depends upon the presence of minute living particles in the atmosphere. Now, if by the use of germicides we can prevent these changes from occurring as already stated, why not, as a result, the compound fracture heal as a simple fracture. This result I attempted to obtain by the treatment before referred to.

That the roller bandage has been objected to I am well aware. I will refer to two cases that are classical, the one reported by Albucassis, the other by Sir John Bell.

The case of Albucassis, the melancholy story of the black eunuch belonging to one of the princes of Arabia, who having fractured his leg near the ankle-joint, had it bound up very firmly with compresses and above the wound. Strict instructions were given not to undo the rollers; from the stricture of the bandage there came on gangrene of the limb. In 1801 John Bell remonstrated against rollers and referred to a boy having a compound fracture of his arm, he says. "the surgeon to whom I referred the case bandaged the fracture with a roller, and at my morning visit I found the fore-arm bound more firmly than a mendicant's leg, the black skin appeared through the interstices of the roller, and the arm fell into total gangrene." In almost every book on fractures since 1801 we have a graphic description and representation of the gangrenous arm referred to by Bell, and the leg referred to by Albucassis. These cases were the result of constriction and not of compression. It may be well to clearly apprehend the distinction between constriction and compression. The first is hard, sharp and painful, it strangles and destroys, while the latter comforts and repairs, it is elastic, soft and gradual; it soothes an injured part; it conduces to healthy innervation and circulation; prevents inflammatory effusions; promotes absorption and controls muscular contraction. In fact it enables us to turn the blood serum, and what would otherwise be waste substance and a danger to the patient, into materials by means of which the reparative process may be quickly effected in the injured tissues.

Amputation.—The treatment of wounds has undergone such a complete revolution that we are compelled to re-cast the doctrine of amputation in compound fractures. Too many limbs are sacrificed by a too hasty resort to the amputating knife. The "knives-men" are still abroad in the land and I regret to say that many of them are found along our railway lines. These have failed to notice that conservative surgery has been carried to a point formerly deemed impossible. MacCormac says: "The great improvements introduced of late years in the manner of treating the wounds have now rendered it practicable to save many cases—even of the most serious injuries, cases of compound fracture for example, and wounds of joints—from the mutilation which amputation of necessity entails."

Wyeth "The present rapid advance in the science of surgery and the greater perfection in its art declare that the time is not far removed when amputation for other causes than gangrene will be comparatively rare."

A surgeon should always remember in deciding whether amputation shall or shall not be performed that upon his decision depends the future of the patient, whether he shall be a comparatively helpless cripple or perhaps be sentenced, himself and family, to pauperism, deprived of the enjoyment and comfort of the performance of those movements which are held in estimation only second to life itself.

Dr. George K. Johnson,
Surgeon-in-Chief, G. R. & I. R. R. Co.,
Grand Rapids, Mich.

Dear Sir:—I herein report the case of Paul Ribble, employed on the G. R. & I. Railway. He was injured on the 26th of May, 1890. The car being loaded with heavy lumber, the brake being defective, would not catch, and when the car upon which he was collided with the forward part of the train, the lumber slid forward, a board catching his leg and forcing it against the brake-staff, producing a compound comminuted fracture of the left leg; the tibia was comminuted, and the fibula sustained a fracture. He was conveyed to the St. Joseph Hospital, and placed under the influence of ether while his leg was dressed. The tibia was carried away for the space of 2½ inches; the upper and lower ends presented the condition known as dentated. Passing my finger deep down in the wound, I found pieces of the tibia entirely detached from the periosteum. These pieces (four in number) I removed; one large piece 2½ inches long, spear-shaped at both ends, and three smaller pieces. After placing them in a basin containing a warm solution of carbolized water, the limb being carefully cleansed and placed in its normal position, while firmly held, I placed the bones as nearly as possible where they belonged. I dusted the part with iodoform, placed protective over it, then a sheet of carbolized cotton, and over this six or eight layers of bichloridized gauze; over this a thin bandage to retain everything in place. I now proceeded to place over all the immovable dressing, using for the purpose a plaster of Paris bandage; this hardened in thirty minutes.

The dressing was allowed to remain twenty-eight days without interference. During this period the pulse remained 75, —never varying, and the temperature at no time deviated from 98.5°; sleeping well, free from pain, appetite good, cheerful and contented during all this period.

June 23, at 2 P.M., I proceeded to remove the dressing, cautiously avoiding all unnecessary movement. The wound was healthy, not one drop of pus; granulation had extended over all the replaced pieces of bone, except one small fragment, which presented a white surface. Union had progressed so far that the fibula was intact, and the tibia, at the point of fracture, was firm beyond my expectation; no swelling nor abscess presented itself; the largest piece of bone had disappeared beneath the granulating surface.

July 7, 1890, I removed the dressing for a second time. I found the wound in the soft parts filled up and firm union of the bone, the replaced pieces remaining, but still somewhat visible. The smaller piece visible at the first dressing much lessened, and the larger piece disappeared; no pus nor abscess present.

I may add the piece of bone next largest in size was not entirely covered by granulations.

Pulse and temperature normal, appetite excellent, sleep undisturbed. The patient's condition all that could be desired: so far not one untoward symptom has presented itself.

Dr. Ricketts, of Cincinnati, said he had read two papers in which he took the ground that in cases of doubtful fractures the surgeon had the right to make the exploratory incision. If, in a case of compound fracture, we can return the dislodged bone and have union, there is no reason why, if there be two or three fragments, the surgeon should not cut down and wire them together. If we are clean there is hardly any limit to what we can do. He was glad to know that Dr. Myers did not use wire in his case, but he thought that in the majority of cases silver wire should be used to hold the pieces in position. The question of operation is a difficult one in railway surgery, where the medico-legal considerations are so great.

Dr. Edwin Ricketts had heard some surgeons say that the bones will not unite if the periosteum is not in place. He could not understand why this should be, if in abdominal surgery portions of the peritoneum are taken off and nothing thought of it.

Dr. North, of Michigan, said he had seen a great deal of railroad surgery, and he strongly advised against the use of the knife if it can be avoided, even if the products of ulceration flow out of the wound. Even a year afterwards an operation can be successfully performed, if necessary.

Dr. Ricketts, of Cincinnati, added that in operation on the skull, the button of bone is returned without the periosteum, and union takes place.

Dr. Griffith stated that he had used decalcified chips of bone and had bone develop from them, and he did not think the periosteum was necessary.

Dr. McCaul, of Michigan, reported a case of trephining in which he returned the button without the periosteum, and the wound is perfectly sealed to-day.

Dr. Emmett, of Iowa, thought there was no longer any question as to bone grafts growing. He had seen cases in which Senn's decalcified bone grafts were used with perfect success.

The chairman, Dr. Gaston, stated that his observations in this line confirmed the views to which he had just listened. He related a case of extensive suppuration along the tibia, denuding two-thirds of the anterior part of the bone of its periosteum. Amputation was proposed, but it was decided to wait, and to-day the case promises complete recovery.

Dr. Emmett related a case of which he had read, in which a patient with a seriously injured foot was advised to have it amputated, but refused. Gangrene set in and the leg had ultimately to be amputated above the knee. The man sued the physician for damages, on the ground that it was the physician's duty to use his own judgment. He won the suit and the Supreme Court sustained the decision, saying that the surgeon was liable for damages, as the patient could not be supposed to know whether amputation is necessary or not.

Dr. North inquired as to the course to pursue if, in spite of every treatment, non-union continues.

Dr. Duffield, of Detroit, stated that if the Supreme Court of the State of New York decides that a patient can say that he will not have his limb amputated, and then holds the surgeon responsible for not operating, the surgeon occupies a peculiar position. He had always contended that the patient should decide. The best way is to call counsel, tell the patient their decision, and if he refuses to abide by it, let him get another surgeon.

Dr. Ricketts, of Cincinnati, replying to Dr. North, stated that mercuric chloride in large doses internally would cause union of the bone.

Dr. Myers said that he has had good results from sawing off the extremities of the bone and nailing them together. He had seen Mr. MacEwen, of Glasgow, after trephining, break up the button into small fragments and replace them. He thought it would always be better to replace any fragments removed, and recalled a case of trephining in which he did not replace the bone, and now, eight years after, there is a concave surface which is making pressure, as is shown by commencing paralysis.

Dr. Ridlon, of Chicago, speaking of non-union, referred to two cases of compound fracture in which non-union persisted in spite of all the numerous plans tried. His plan was to put the limb in position and hold it there, preventing motion laterally and longitudinally, and then constrict the limb above the point of injury by a band, producing œdema about the injured part. The legs were allowed to hang down, and in both cases union was perfectly solid. Eighteen months and a year respectively elapsed between the injury and this treatment. Thomas reported forty cases so treated successfully.

Dr. Milton, of New York, related a case of non-union cured by the patient being allowed to use the leg.

Dr. Graves, of Michigan, thought that cases of non-union were really cases of delayed union. He had seen many cases in which the bones took months to unite.

Dr. Smith, of Michigan, believed that the upright position, together with getting the patient out into the fresh air, materially helped cases of non-union.

The Chairman reported a case of non-union cured by forcibly rubbing the ends of the bone together so as to excite inflammatory action.

GUNSHOT WOUNDS OF THE BRAIN.

Read in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June 8, 1892.

BY C. E. RUTH, M.D.,
OF KEOKUK, IOWA.

Gunshot wounds of the brain have always been considered almost of necessity fatal, and when we review the surgical history of our late war and find among hundreds of brain wounds, that not more than ten cases made partial or complete recovery, we need not be surprised to find the general concensus of medical opinion to the effect that nothing could be done in those cases but to make the patient as comfortable as possible, while the fatal result was confidently awaited.

Less than ten years ago, I have heard leading surgeons stand before medical classes and say, when a missile has entered a cavity, never explore for it. None would think of following that advice in regard to the abdomen to-day. We may not hope to accomplish, in gunshot wounds of the cerebrum, as much as has been or can be accomplished in abdominal gunshot wounds. Yet I think there is evidence to prove that cases in which missiles have entered or passed through the brain, are not necessarily so hopeless as has been believed. Many do not die immediately, and when they do not, they are entitled to as much consideration and effort to spare their lives as for other grave injuries.

All our standard authorities on surgery, which I have seen, except two, Wyeth and Treves, agree that we are not justified in attempting to follow a ball that has entered the brain. That its track can not be followed without doing more damage to the brain than the missile would do if left alone. That the finding of a ball that has entered the brain is simply a piece of surgical good fortune or accident, and not due to the operator's diagnostic or operative ability.

The advance ground that Wyeth and Treves take seems to be based wholly on the case of Fluhrer, in Bellevue Hospital, in 1884, in which he followed the track of a ball some distance into the brain and removed a trephine disc from the opposite side of the head from the point of entrance, at a point slightly below the spot he expected the ball to have struck, and found the ball imbedded in cerebral tissue and removed it.

Case 1.—March the 3rd, 1891, I was called by Dr. F. L. Darrow, to see E. C., aged eighteen, who had been shot sixteen hours before by a thirty-two calibre pistol at short range. The ball entered at the outer canthus of the right eye, through the frontal process of the malar bone, and passed upward and backward into the brain. From the position of the parties concerned in the shooting, appearance and course of the wound through external soft and osseous tissue, the course of the ball through the brain was towards the opposite parietal eminence. The only symptoms of compression were slight slowing and irregularity of the pulse, which disappeared on the removal of a coagula occluding the wound and discharge of cerebral tissue and fluid blood. Temperature, pupils, motion, sensation and coördination were normal. For two weeks he remained rational, slept and ate well, pain slight. At the end of that time he began to show evidence of septic trouble with pyrexia of moderate degree, followed by anorexia and rapid failure of strength. The wound had not been allowed to close, but not being satisfied that the drainage was as complete as it should be, I carefully introduced a director four inches, and replaced it with a drainage tube. The director did not pass in the direction I had mapped out for it towards the opposite parietal eminence, but at an angle to its line of incidence of about thirty degrees. Noting no improvement in his condition, two days later I introduced a drainage tube six inches without any marked resistence. I did not know how much resistence a normal brain should offer, but was satisfied that the force I had used was so slight that I was certainly in the track of the ball. Still noting no improvement in his condition, but on the contrary rapid failure, I was satisfied that there was a pus cavity about the ball and determined to go still deeper for drainage purposes, and passed my director, and afterward drainage tube to the skull behind. The case by this time was so desperate that no time was to be lost, as he might apparently die at any time, I determined to try and find the ball. I shaved the occiput, carefully passed a gum director until it was resisted by the skull posteriorally and with a straight edge sighted the projecting end of the director vertically and horizontally, and drew a line across the occiput at right angles to the projecting portion of the straight edge in both positions. The point where the lines crossed I expected to indicate the position under which rested the point of impact of the bullet, and the tip of the director. On removing a half inch disc there was a discharge of pus to the amount of one to one and one-half ounces through a hole in the dura mater made by the impact of the bullet, and the mark of the bullet was plainly shown by a lead deposit on the inner side of the disc.

The center of impact was missed by the center of the trephine disc not more than three-sixteenths of an inch. The disc was removed at the junction of the parietal and occipital bones, one inch to the right of the median line. A drainage tube was passed entirely through the middle and posterior lobes of the brain on the right side and irrigation practiced twice daily with sterilized water and hydrogen peroxide. Appetite improved and pyrexia grew less for four or five days, during which time he was perfectly rational, but the improvement was not maintained and he died from exhaustion ten days after the operation and thirty days after the shooting occurred. The ball was procured at a dressing a couple of days after the operation. The ball being free in the abscess which formed around it made it impossible to procure it at the time of the operation without destroying normal cerebral tissue, or the removal of another trephine disc to procure more room. His condition was not such as to warrant further operative interference at that time. Unfortunately no post-mortem could be obtained.

Case 2.—May 4th, eighteen hundred and ninety-two, was called to see Fred. S., German, aged eighty, who had shot himself about thirty-six hours previously with a thirty-eight calibre pistol. The ball entered one-fourth of an inch to the right of the median line of the frontal bone and one and one-fourth inches above the supra-orbital margin. Bleeding had been profuse but had entirely ceased before I saw him. A few hours after the injury he appeared for a time quite rational and talked some. When seen by me his pulse was one hundred and eight to one hundred and twenty, of fair volume, respirations irregular and semi-comatose. Left eye normal, right palpebral tissues greatly swollen and discolored from hæmorrhagic extravasation, the eye markedly more protuberant than its fellow, and pupil insensible to light. I increased the size of the external wound and removed burnt and discolored tissue from its margin, together with a small bullet fragment. On opening the wound there was a small hæmorrhage which carried out some loose cerebral tissues. A three-sixteenths of an inch porcelain-tipped probe passed readily along the bullet's track downward and backward through the frontal sinus into and through the anterior inferior portion of the first frontal convolution, through the junction of the ethmoid, frontal and body of the sphenoid bones on the right side, and lodged beneath the pharyngeal mucous membrane behind the right posterior nares, from which it was readily removed. A drainage tube was passed through the wound and allowed to remain. He survived the shooting sixty hours and was semi-comatose after the first ten hours with involuntary fæcal evacuations and urinary retention. The gravity of the injury in one so old, enfeebled by insufficient food. extremely un-hygenic surroundings before and after the shooting, makes comment on the result unnecessary. There was not the slightest difficulty in following the ball through the cerebral tissue, the resistance being ample to enable me to determine that the probe was following the bullet's track.

Case 3.—In the *Vis Medicatrix*, published at Des Moines, Iowa, February or March, 1892, Dr. Conniff reports the case of a man on whom he held a post-mortem and found a conoidal ball weighing one hundred and twenty-six grains lodged in the left posterior lobe of the cerebrum. It had passed through four or five inches of bone and soft tissue before entering the brain, and was so far spent as not to be able to reach the opposite side of the skull from this point of entrance, and probably had nearly or quite all of the grease and dirt removed before it entered the brain, and was carried twenty-nine years, the patient dying from other causes. This is, I believe, the longest period which any man has carried a ball in his brain and retained a moderate degree of physical and mental ability. Yet he complained of great pain throughout a considerable of the period, and always claimed he could feel the ball in his brain.

War histories, thus far, are of but little aid to us in determining what should be the mortality of gunshot wounds of the brain, for feeble, if any attempt, has been made to treat such wounds aseptically. In our surgical history of the Rebellion, statements are made to the effect that the wound was healthy and suppurating nicely when applied to wounds of the brain, while now there is scarcely a surgeon to be found who does not prefer to have all wounds heal without pus formation. The case of Fluhrer, as well as my cases, prove that a ball may be followed through the brain and in some cases removed. When a ball enters the brain, it may confidently be expected to pass through the cerebral mass in a straight line until it strikes bone, lodges by the resistance the cerebral tissue offers, or is deflected by the falx-cerebri or tentorium. If the missile takes a straight course through the cerebral tissue, all instruments, probes, directors and bullet forceps should be straight, so that the position of their tips may be accurately known, and it will be wise to have them graduated on the shaft, to enable the operator to determine the degree of penetration, and being straight, if the ball be deflected at any point, it will be shown by the probe or director persistently hugging one side of the wound of entrance, to enable it to make the curve and follow the course of the projectile, thus indicating the direction of deviation, and when that is known its extent may be determined by bending the shaft if a suitably tipped probe be used.

In Treve's "Operative Surgery," just published, the statement is made that "the chief end effected by the surgeon in a large number of cases consists in providing free drainage and not in removing the foreign bodies, the presence or position of which is uncertain. It is a question which can do the more harm, a motionless bullet (which may in time become encysted), or a probe driven hither and thither through the brain substance."

He advises the use of an aluminum probe, as advocated by Fluhrer, and states that it must be allowed to pass by its own weight alone. There can be no excuse for thrusting a probe in any direction through normal brain tissue in the search for a ball. If the probe be of proper size and shape, it will give a definite and readily appreciable resistance before making a false passage. I am aware that this may be thought altogether too sweeping a statement, when the general opinion among medical men is to the effect that cerebral tissue cannot offer resistence to a probe sufficient to be appreciated by the touch, "except it be especially skilled," as one authority puts it. It would appear to be a very difficult matter to find a man specially skilled in this department. I found by careful test of many sections of brain in which post-mortem changes had not softened it, and no hardening fluid had been used upon it, that a hemisphericaly tipped probe of one-fourth inch diameter, required from two and one-half to three ounce weight to produce penetration, and one and three-fourths to two ounces to cause it to pass between the convolutions. This sized tip is sufficient to use in following any ball from thirty-two calibre upward, with a resistance to penetration that a very unskilled touch ought to appreciate, and if he cannot, he can hang on weights within safe limits, or abandon the case to some one better suited to the work, instead of trusting to his extremely uncertain touch. A three-sixteenth of an inch probe will require, under the same conditions, from one to two ounce weight to cause penetration of sulci or normal cerebral tissue, and will answer for all the small rifle balls, but both should be porcelain tipped for obvious reasons, and be carried by a small aluminum shaft, so as to give the least possible weight to the probe, and as slight lateral friction as possible to the collapsed canal, that all the resistance can be appreciated by the hand manipulating the probe, and not to be compelled to take up an appreciable part of it in resisting weight, and to have as nearly as possible all of the resistance at the probe's tip.

The external wound may give but a poor index of the course the ball takes through the brain, even though the individual shot and the one doing the shooting at the time the weapon was discharged may be known with a fair degree of accuracy. All men who have given the subject any attention, know that after a ball of any ordinary calibre passes into or through the brain there is a collapse of the walls of the track to complete filling by débris and normal cerebral tissue that has prolapsed into the track of the projectile.

Wyeth states that a gum catheter, presumably one such as is used with a stylet, a few sizes smaller than the missile, was as good a probe as could be procured. It would give more resistance to penetration than the ordinary probe. The principal objection to it is that the tip is frequently imperfect, that the shaft is the same diameter as the tip throughout, and the collapsed bullet hole produces more and more friction and consequent obstruction to the advance of the probe. It follows that before the probe advances far, the resistance may be so multiplied that it is impossible to determine whether your resistance is at the tip of the probe or in the lateral walls. Such at least has been the experience in my hands in one experimental case, in which, for the above reasons, I made a false passage. Yet in the first operation I made on the living subject and followed the ball successfully, I used a gum catheter with a stylet to keep it straight.

If a ball be completely flattened and far spent, its course may be like a boomerang through the brain; but such balls will seldom enter the brain at all, and all others will take a straight course.

As an aid to accuracy in locating the nearest point on the scalp to the tip of a probe which had been introduced along the ball's track in the brain, I had a straight bar made ten inches long with two points three and one-half inches long projecting in the same line at right angles to the bar, one point being curved and adjustable, so that when it was placed over the head it could be adjusted to the size and shape of the head; and the bar sighted, with the projecting end of the probe the same as though it were an ordinary straight edge; and with one end projecting by the side of the probe and the straight bar over the top of the head sighted with the probe, a mark may be made by the side of the opposite point which must pass over the tip of the probe, and by repeating the sighting over the skull ninety degrees from the former point and again drawing a line as before, the lines must cross each other at right angles, and the point of crossing will mark the position of the tip of the probe if the sighting be accurately done. An ordinary straight edge may be used as previously mentioned, yet this is quite an aid to additional accuracy.

If the ball strikes at right angles to the surface, or within fifteen degrees, and does not penetrate, the missile will probably lodge at the point of impact or within one-half inch of said point, and will but rarely rebound. Accepting Fluhrer's statement that a ball would rebound, I was surprised to find after firing balls into skulls, and they did not produce penetration of the opposite wall, that they remained where they struck or glanced, but did not rebound. In rare cases they re-penetrate the brain after striking the opposite bony wall; but they almost invariably do it by glancing from the point of impact, at angles to the line of incidence of more than ninety degrees. I could on no account consider that a ball rebounded, unless it re-penetrated the brain by passing back from its point of impact, at an angle to the line of incidence of less than ninety degrees.

Not finding skulls sufficiently numerous on which to experiment, I had a hemisphere made of sheet steel with every possible facility made for aiding in causing bullets to rebound, and fired twenty-two, thirty-two and forty-four calibre shots into it at all angles; and in all the varying velocities which the bullets would stand, from slight deformity to complete flattening of the balls. I had no bullet rebound that was not flattened at least one-third, and a velocity which will produce one-third flattening will nearly always produce penetration of the skull. In those which did rebound it was in varying degrees from almost the exact line of incidence to near a right angle. The distance which a ball will move from its point of impact after passing through the brain must depend upon its velocity, angle of incidence, the surface of contact, and shape of the ball. Unless the force of impact be great, the dura will not be cut, but will brobably be congested and the ball may remain between the dura mater and the brain. There can be no objection in any such case to opening the skull opposite to the point of entrance at the point of secondary impact of the bullet, and establishing drainage and removing the bullet if it be accessible. *Whether the bullet be found or not, we can expect no* harm to come from the trephine hole which will probably prevent the formation of an abscess around the bullet, and its destroying the life of the patient. as it did in my case, after the boy had shown himself capable of recovery from the damage done to his brain in the missile's passage: but he could not recover from the abscess and cerebral traumatism, and the abscess could not drain through the entire cerebral mass along a collapsed bullet hole.

Had I removed the disc earlier, the ball would have been readily found, the track of the wound could have been drained, and the formation of an abscess around the ball, or at its point of impact, made an impossibility. After a ball has traversed the brain until it strikes the opposite bony wall, if by glancing or rebounding it is again caused to penetrate the brain, it can be expected to do so in a straight line from its point of impact, and may be followed in its secondary track to its point of lodgment, with as much ease through a trephine hole as it was originally followed from its point of entrance to where it was deflected from its course. Should it strike with considerable velocity at an angle to the horizontal of less than thirty-five degrees it may sweep around the skull in close contact with the bone for a great distance, passing probably between the dura and piamater, and leaving but little evidence to show the track it took. Occasionally balls are so far spent as to lodge in the brain at some point after gaining entrance before reaching bony resistance, and again after deflection, when it becomes necessary to remove them by some means.

I found I had no forceps at my disposal which could be operated through so small a space as the average bullet hole, without lacerating the cerebral tissue. So I had Truax & Co., construct me a bullet forcep which could be operated through a cannula smaller than a twenty-two calibre pistol ball, and yet the jaws be opened wide enough to grasp firmly a forty-four to fifty-five calibre ball. The jaws are operated on the same principle as is used in some vertebrated or flexible œsophageal forceps, but the shaft is straight and not flexible, so as to enable the surgeon to determine with certainty the position of its tip. I find that it requires considerable experience and manipulative dexterity to readily grasp and hold a missile in so soft a tissue as the brain without doing damage to the surrounding brain substance. I would not recommend anyone to attempt to grasp a bullet and extract it from the brain of the living, unless he had some experience in the work on the cadaver. I would not advise the use of a trephine less that three-fourths of an inch in diameter for removing a disc over the point of impact of a bullet, as it gives insufficient room for examination with the finger or further operative interference; unless another disc be removed, which requires considerable additional time, or the opening be enlarged by the rongeur. I have been able to trace no evil results to the use of the rongeur, yet in my experience with it I have been compelled to separate the dura-mater from the bone for some distance beyond the bone gnawed off; and should the wound suppurate, it makes a point difficult to drain and increases the liability of an unfavorable issue. A large disc can be removed almost as quickly, easily and safely as a small one, and if it be removed with as complete knowledge as is obtainable of the direction the ball will take from the point of impact (if it moves at all), will probably give ample room for all further operative work in that case. The disc should not be replaced for reasons apparent to all. Cerebral localization is usually of little use in cases of this kind, except rarely when abscesses form, and then it is too late for operative measures to save but a very small per cent. of cases. If the ball be small, and especially if it be round, has passed through considerable tissue before reaching the brain, so that one may be tolerably certain that it carries in no grease and dirt, and no symptoms develop, it may be allowed to remain, otherwise it should be followed and removed if possible. In a majority of the cases pieces of bone will be broken off and carried into the brain and lodge at various points along the bullet's track, and they should be removed when accessible, as they must of necessity act as foreign bodies, producing considerable irritation, and probably suppuration to aid in disposing of them. Re-penetration of the brain by a glance or a rebound can be expected to occur but once. The ball will pass almost invariably in a straight line from where it glanced or rebounded. *There exists a necessity for trephining but once,* unless it be necessary to trephine at the point of entrance, for the purpose of giving more room for elevating depressed bone.

The operative rules laid down in standard authorities regarding the enlargement if need be of the wound of entrance, removal of spicula of bone, trephining, etc., are too complete to justify an attempt on my part to improve on them. I have purposely omitted from this paper the tiresome details of the experiments I have made in this work, and if necessity require it, I may at some future time place them before the profession.

SUMMARY.

1. That a ball can be followed in its course through the brain.
2. Having been followed to its point of impact on the opposite side of the skull, a trephine disc should be removed, drainage be established and the ball removed if possible.
3. That the probe is best which gives the greatest resistance to penetration with least possible lateral friction on its shaft by the collapsed canal.
4. That hemispherical front, porcelain tip, and aluminum shaft answers the indications for lead detection (resistance if of proper size, weight, etc.,) required in a probe, better than anything else.
5. That one intending to follow balls through the brain should thoroughly familiarize himself with the resistance the normal brain offers to penetration by the probes he expects to use, that he may know when he is applying force within safe limits.
6. That he should frequently grasp and remove balls and pieces of bone with the forceps of his choice on the cadaver, before attempting it on the living human subject.

REPORT OF A CASE OF TALIPES EQUINO VARUS.

Read before the Section of Surgery and Anatomy at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY B. MERRILL RICKETTS, Ph.B., M.D.,
OF CINCINNATI, OHIO.

W. D., a typical Kentucky lad of fourteen years of age, consulted me on Sept. 1, 1891, having suffered from time of birth with talipes equino varus in a most aggravated form.

The foot was turned straight backward, so that the weight of the body came directly upon the astragalus. This state of affairs necessarily caused the plantar surface of the foot to be thrown upward to such a degree that the under surface of the toes was the only part that touched the ground while standing erect.

The left foot, he said, was at the time of birth, as greatly deformed as the right, but by rubbing and manipulating it by those having him in charge, cured it.

I found upon examining the left foot that the ankle joint would allow of more motion in all directions than a normal joint should admit, thus proving to my mind that there had, at one time, been some deformity of the left foot.

However, this boy was able, with an ordinary pair of shoes, to romp and climb the hills as fast and easily as could his ordinary companions. With this ability to enter into the sports, he had the sense of pride which is possessed by all Kentuckians, and was willing to undergo almost any amount of suffering to have the deformity corrected.

I advised an operation, and after some explanation obtained the boy's consent to operate. Chloroform was used as the anæsthetic, and the operation was made on Sept. 2, 1891, at 10 o'clock A.M., in the following manner:

A Barton's bandage was applied to make the operation a bloodless one. An incision was made upon the external aspect of the instep, about two inches in length, extending from the lower end of the fibula in the direction of the lower end of the tibia, which brought me upon the ligaments and tendons connected with the joint.

I did not divide any of these tissues, merely crowding them aside so that they could not be injured in the process of extracting the bone, which I thought would be difficult.

The astragalus was found to be hard and much deformed, so that its outlines were very indistinct. However, there was but little difficulty experienced in dividing the bone, it being found impossible to extract it without dividing the ligamentous tissues and extending the cutaneous incision, both being steps which I wished to strenuously avoid. After removing the bone, I endeavored to bring the toes forward, which, however, was not very successful, as the tendon Achilles was almost obliterated, the little remaining being very dense. I found it necessary to divide all of the tissues posteriorly before the first could be brought forward in a normal position. When the foot was put in this position, the plantar facia was found much contracted, so much so that I divided it completely. The normal position was maintained with straps passed under the foot in close proximity with the toes, and made fast to hooks woven in a plaster extending from the middle of the thigh to below the knee. This proved to be a great error, as the pressure was so great from the tendency of the toes to turn backward, that a slough ensued, which complicated matters very much.

At the end of the fourth day the strap was removed, its damage not having been detected before this time. The operation was made under hot filtered water irrigation, and the dressing of the same character.

The patient recovered from the effects of the anæsthetic, but suffered a great deal. Although drainage was not provided for in this case, I would not fail to use it in another. Every time I have failed to make this provision regret has followed. It was found necessary to open an abscess on the top of the foot, under the hard callous, which had been formed by walking on it, which was at one time the sole of the foot.

Peroxide of hydrogen and water irrigation were extensively used, and the temperature remained less than one hundred after the tenth day, it previously having reached on one occasion one hundred and four. His recovery was now uninterrupted, the foot keeping its normal position without support. He was on crutches at the end of the fourth week, and left the hospital at the end of the tenth week, with but a small sinus which has since healed, as stated in a recent letter from him. A shoe is worn, and he now goes about without the use of crutches. I have not learned of one so old as this lad being operated on in this manner (removal of the Astragulus).

In my mind it is the most desirable operation to make in a certain class of talipes, that class including those cases where tenotomies give but little promise. The slope of the foot is preserved; the joint more useful, with comparatively no more danger.

The tibia is made to rest on the os calcis by the removal of the bone, the shape of which has been changed to such a degree that it will never allow the sole of the foot to rest evenly upon a plane.

AMPTUATION OF SCROTUM AND CIRCUMCISION.

(Referred to me by Dr. Garner, of St. Joseph, Mo., August 9, 1890.)

Mr. F. P., æt. 22 years, white, United States, active mind and in fair physical condition. Height 5 ft. 8 in., weight 130 lbs., brown eyes and dark brown hair, and of a nervous temperament.

He was free from syphilis, and with no predisposition to tuberculosis. Drinks tea and coffee, occasionally indulging in a glass of beer or wine, and is an inveterate cigarette smoker.

He stated that he had consulted nearly all the leading surgeons and dermatologists of this country without obtaining a diagnosis, or any encouragement in operative interference.

I found upon examination that the scrotum was thickened and about six times its usual size, as was also the prepuce, the latter not having been retracted for years.

Papillomatous growths, varying in size from the head of a pin to a large pear, studded the surface of both the penis and scrotum. There were also many small angioma.

This thickened papillomatous and angiomatous condition existed on the skin of the right leg from the apex of Scarpa's triangle to the toes, gradually becoming more extensive as the foot was approached. The greatest trouble, however, was between the upper third of the leg and the ankle.

Upon removing the bandage, which had been used constantly for years, and which was necessarily made tight, the entire leg would immediately begin to swell, and continue to do so until it would become twice its normal size, having a tense glistening appearance, accompanied by considerable pain and discomfort.

If the cuticle was abraded, lymph would flow continuously until from 5 to 30 ozs. would have escaped. This was also the case if a papillomatous growth was broken, or the skin punctured with a needle. This exudation was very annoying, as it would occur on the slightest provocation and could not be controlled, ceasing only of its own accord. The lymph was the color and consistency of thin cream, slightly tinged here and there with blood. It was bitter, and crystallized on evaporation.

When 18 months of age an abscess formed in the right groin, which was freely incised by the attending physician. From this dated the trouble in the leg, scrotum and penis.

The patient would have three or four severe chills during each year, followed by a temperature ranging from 103° to 104.5°. Delirium would accompany the chill and fever for from twenty-four to forty-eight hours.

It was found upon close inspection that the leg was larger and more uncomfortable just preceding one of these attacks. The quantity of urine voided during the time would be less for the first twenty-four hours, but would then flow in abundance. The appetite was poor, the skin clammy and of a light copper hue, the eyes glassy, and his mind dull and inactive; bowels constipated, with great tenderness in and about the right iliac fossa. There were also extensively enlarged glands in this region.

Under the circumstances, I advised complete circumcision and scrototomy at the same time, explaining how it might be possible to have a great loss of lymph from the severed integument. However, consent was given to remove the prepuce. If this did not cause trouble, he would allow me to amputate the scrotum later on.

Circumcision.—Within a few days he presented himself for operation, which was made painless with cocaine. An incision was made upon the dorsum, after which the lateral incisions were made, thus baring the gland entirely. There was no blood or flow of lymph whatever to complicate matters, and the patient made a rapid recovery, being on his feet constantly after the first three days. Numerous small papillomata were found distributed over the surface of the gland, many of which were of a pearly white, while others were reddened, giving the appearance of angiomæ.

His anxiety was now relieved and the irritable condition of the gland and prepuce at an end, all of which gave him courage to undergo the more severe operation. He gained five or six pounds during the following two months, at the end of which he decided to have the scrotum amputated. This was done in November, 1890, in my private hospital, in the following manner:

After applying a King clamp, one-third of the scrotum was removed and the edges brought together in the usual way. It was found that the vascular supply was much greater than in a normal scrotum; some of the vessels being twice, while others were three times their natural size. In consequence thereof considerable hæmorrhage ensued.

It was found, however, that the exudation of serum was slight and of but little importance, while the principal bleeding point was obstinate.

The patient rallied nicely from the anæsthetic, chloroform, and complained but little until about 11 P.M., when he suffered considerable pain. There was constant oozing from the wound, with extensive swelling of the entire scrotum. This led me to suspect concealed hæmorrhage about 3 A.M., when I cut the stitches to find the scrotum distended with blood clots. There was also arterial hæmorrhage, evidently from the same point as at the time of the operation, at 10 o'clock of the preceding A.M.

The cavity was evacuated and exposed to the air, when the hæmorrhage ceased. The stitches were again adjusted and the wound dressed with dry boracic acid. He remained in the house for one week, at the end of which time he left for his home. Part of the wound healed by granulation.

During the following year he had but two or three chills followed by fever. He gained flesh, felt more comfortable, appetite better, slept better and felt entirely satisfied with the result.

The operations were not with the view of curing the patient—merely to relieve. I feel assured that the end justified the means.

I believe I was wholly responsible for this accident, in that had I been more careful in torsioning this artery, the unpleasant hæmorrhage would not have occurred.

NEURECTOMY OF THE POPLITEAL SCIATIC NERVE FOR PAINFUL NEUROMA AS THE RESULT OF GUNSHOT INJURY.

M., æt. 27 years, a tinner by occupation, consulted me on August 14, 1891, stating that he had been shot two years previously through the leg, and that he had suffered excruciatingly ever since. He also stated that by the advice of the attending physician he had become addicted to the habit of taking morphine hypodermically until he had reached the daily maximum quantity of fifteen grains. This statement was easily verified by the innumerable pigmented points upon the legs where the hypodermic had been inserted.

Upon examination I found that the ball (38 calibre) had passed obliquely through the left leg, entering on the inner side three or four inches above the condyle, anterior to the ham string of the biceps, passing upwards at an angle of 45°, making its exit externally about the middle of the thigh.

At the time the revolver fell from the counter and exploded (for this was the way the accident occurred) he was standing erect. Immediately upon hearing the report he felt a severe pain in the toes of the injured leg. Thinking that he was shot in the foot, he had his shoe removed, but could not find anything to indicate such a state of affairs. He did, however, find a stream of blood flowing down the leg, indicating that the injury was higher up the member, and which led him to the exact point of entrance of the ball. The pain within an hour or so became equally distributed over the foot and that portion of the leg below the injury.

As pain is the thing for which the physician is most consulted, he went from one to another, trying every remedy that might be suggested, without relief; hence, the advice given by the physician in a fit of desperation, to relieve himself of the responsibility of caring for such a patient. He would take an injection wherever he might be, when the pain came on; whether it was on the house-top or in the shop. I saw two of these doses taken, satisfying me that each contained five grains.

Operation.—Aug. 20, 1892. Leg shaved and cleaned as well as possible, chloroform administered and rubber bandage applied from toes upward. An incision four inches in length was made in the median line posteriorally, encroaching upon the popliteal space. The skin being divided, I tore my way through the tissue at once, exposing the nerve, which was three times its natural size, for a distance of one and one-half inches. Upon examination I found that the nerve divided much higher up in this case than any I had ever seen, fortunately for if it had not been both branches would have been divided. I found that the external branch was the uninjured one, and that it was adherent to the internal one for a distance of three inches. A section one and three-fourths inches long was excised, which included the entire enlargement. Before dividing the nerve, a silk thread was passed through it, on either side of the enlargement, so that the ends could be brought together by flexing the leg at right angle. The leg once flexed, the ends were coapted and a silk suture applied on each side of the central artery, that it might not be injured. I then passed another silk suture through each stump, one inch from their ends and tied them, so that too much tension would not be brought on the two smaller ones—distributing the tension. The external branch being much slackened by the flexion was left to care for itself. A drainage tube was placed in the wound and silk suture used to close it.

The leg was kept flexed by a strap about the ankle, attached to a band about the body. Upon rallying from the operation the patient complained of pain, the character of which was similar to that before the operation, so that it was necessary to give one-half grain of codeia at 7 P.M and 9 P.M. following the operation. The use of morphine was forbidden and the use of bromide and chloral resorted to.

The temperature reached one hundred on two different occasions and remained about ninety-nine during the course of recovery. The Faradic current was used with great benefit at various intervals. The drainage tube was removed on the third day and the cutaneous stitches on the fifth day, at which time there was a slight discharge which continued for about fifteen days.

On the twelfth day the leg was let out five or six inches and the patient allowed to sit up. The pain was more severe while the patient was lying upon his back than while sitting up or around on crutches.

He was allowed to be up and about on his crutches every day after the twelfth day. The pain gradually disappeared, and he was allowed to leave "The Trinidad" on Sept. 10, 1892, having been in the hospital twenty-two days.

I heard from him recently, and find that he is free from pain and the morphine habit.

Dr. Ridlon of Chicago, believed that there are certain cases of congenital club-foot that cannot be cured without excision of the astragalus, though some claim that all cases can be cured by stretching and dressing, and others that all can be cured by tenotomy. He had a case in which different dressings were carefully applied with an unsatisfactory result; then tenotomy was done and the foot dressed with plaster of Paris and still the case relapsed, then the open operation *of* Philipps was done, and even then, after wearing carefully adapted apparatus, it relapsed. Finally the astragalus was removed and it was found to be wedge-shaped posteriorly, which accounted for the difficulty in keeping it in position. The result was perfectly satisfactory.

Dr. Sayre, of New York, said that he would not go so far as to say that all cases of club-foot could be cured without removal of the astragalus, but he had never seen one which required it. Even if we have this distorted condition of the astragalus we must remember that at first these bones are soft and malleable, and if the foot is put in correct position the bone will be moulded. He could conceive of cases, where there was absence of different parts of the foot, where removal of parts of bone might be necessary to correct deformity, but in congenital cases treated from the outset, he was of the opinion that no bone operation was required. He had not yet met with an advanced case that required bone cutting operations, and he had seen cases in persons from 26 to 46 years of age, which had been without treatment since childhood. Complete section of the ligaments and all holding soft tissues was sufficient if combined with great force in putting the foot into normal position. The reason why so many cases relapse is because they have never been cured. No case should be considered cured until it can be retained in position without apparatus. Something may be said for operation if the patient cannot afford the time for the slower treatment.

WHAT IS THE RELATIVE INTERDEPENDENCE OF ORGANS OF THE BODY IN HEALTH AND DISEASE?

Read by title in the Section of Practice of Medicine at the Forty-third annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY J. B. HERRICK, M.D.,
OF CLEVELAND, OHIO.

In presenting my thoughts on this subject I am moved with a desire to express to you those things which we have all seen in our professional experience. From those observations we may piece out our conclusions—examine them, and approve or decline their acceptance. By such processes do our minds make progress along the way of truth. The conclusions in the complex problems of medicine are oftener determined by the point from which we start. In giving my thoughts on this subject I may say further that I have no expectation of presenting any new principles but old established ones in a relation from which we may hope to draw profitable conclusions.

The problems regarding disease are so obscure and involve so many and such varying factors that their solution has baffled the skill of wise men of all ages —and as yet, though we have to deal with natural phenomena which present uniformity, except in varying conditions, we have not rested our inquiries upon any absolute principles, from which we can reason with unanimity in the interpretation of facts. Medicine is called an uncertain science, and we confess with some show of truth which result often in most unsatisfactory empyricism in the art. In this we find the varied and conflicting theories of pathology, and also conflicting methods in the art, so that the problem before us is to establish some principles on which we can rest, and art that shall be established so as to require the one practicing it to consider the differences in each case, and apply such remedial means as shall appear reasonable because referable to some accepted principle. It is some such reflections as these that the question of the relative interdependence of organs in health and disease, presents itself for solution. To this inquiry I respectfully solicit mutual attention. We recognize the mechanism of the body as complex; with each part dependent upon another, so that the whole can attain its typical structure and function, only when the several parts each attain their special end. While this is true, it is also obvious that there are degrees of dependence and interdependence among the different parts, which it is always essential to recognize in a pathological and therapeutical point of view.

That the different vital organs are not equally responsible for diseased conditions we readily admit. As all forms of disease must be looked upon as only a disturbed normal process in some organ, or group of organs, an inquiry as to the interdependence of the different parts may be regarded as an essential step in the solution of the problem of diseases. The body is so complex an organism that we are prone to overlook the fact that it is made up of different groups of organs having certain related functions, all of which constitute the phenomena of life. It is a mechanism, and each of its different parts have certain essential functions while others are more or less passive. It is to call attention to this relationship among the different organs, and in doing so to enquire as to the beginning of disease that I present this subject. Recently I was called to attend an elderly gentleman, a watch maker and repairer, who was a shrewd yankee and withal very skeptical as to the skill of physicians to diagnose disease and any scientific guidance as to remedies for their cure. After some general conversation, I asked him if in his experience in repairing watches he had not found [illegible] certain parts of the watch were prone from cer[illegible] peculiarities of contruction or activity of func[illegible]n to get out of order, more easily than others. Were not the diseases and defects of the watch generally found in certain parts? To which he promptly replied, "yes." What are those parts? I asked, "The escapement and mainspring," he said. I took occasion to show him that his body was as distinctly a mechanism as the watch, and that the conditions of health were as strictly dependent upon the organs of the body as the watch for keeping time upon its intricate parts. I also assured him that there were certain parts of the body's mechanism that were prone to disturbance in consequence of which the whole phenomenon of health was liable to be impaired. For the purpose of showing this relationship I have arranged a grouping of the tissues and organs of the body with reference to their mutual dependence. I am aware that this grouping is somewhat arbitrary, and is given only to assist in answering the question before us, and making my thoughts clear. In this arrangement I have made three groups. Under the first group I have placed those parts that are entirely passive and wholly dependent upon other parts for their support. In the first group we have

1. Osseous tissue.
2. Connective tissue.
3. Cellular tissue.

In the second group I have arranged those organs whose functions are active in securing the ultimate end of life,and which contribute to the support of all the others and yet are themselves dependent. In this group we have arranged

1. The circulatory system.
2. The muscular system.
3. The nervous system.
4. The reproductive system.

This group includes those organs that perform the active and responsible functions of life. In the third group I have arranged those organs whose functions are elementary and entirely accessory to the second group. The functions performed by this group are essential for those of the second. If they are in any degree suspended or defective their influence is felt in the functions and they of all others are prone from natural causes to disturbance of the more active organs of the second. The group includes:

1. Organs of Secretion.
2. Organs of Digestions.
3. Organs of Absorption.
4. Organs of Assimilation.
5. Organs of Excretion.

This third group, it is to be observed, includes all the organs which contribute to the marvelous process of transforming the varied alimentary substances included in foods, into blood, which is the first essential material for the nutrition of every part. It is obvious with some such grouping of the organs and tissues for the object intended we are able to appreciate the function of each group and consider the relative dependence of each. For example, it is evident that for normal nutrition and structure the osseous tissue and its group are entirely dependent upon other and accessory parts and processes. All diseases of bone, connective or areolar tissue are always due to certain abnormal condition of nutrition, as blood, blood supply, or nerve influence. Each of the tissues in this first group have passive functions. If other functions on which they depend are normal these will always be normal. If we carry the same inquiry to the second group of organs that have more active functions we find among them certain absolute and uniform conditions necessary for nutrition and normal functions. It may, I think, confidently be asserted without question that if there is a right state and supply of blood and normal nerve force the function of each will be normal; nutrition will be normal, health will prevail in each of the organs of this group. Whichever of the various views of pathology is accepted we should follow along the line of physiology to detect the pathologicial, the normal to detect the abnormal. It is obvious that whatever of morbid material exists and whatever its form, either germ life, necrotic-material or mineral poison, for working its morbid effect, it must be carried to the tissues through the agency of the blood vessels or lymphatics. Accepting this statement, it would seem to follow that the function of the second group of organs will be normal if the functions of the third are performed.

The second group includes organs which are concerned in all of the active operations of life—their action may be regarded as ultimate or for the chief ends of life, and this action always depending upon the coördinate nutrition of all parts, and also those for the completion of these functions themselves.

If my statements are correct, and conclusions accepted, it is obvious that the five processes included in the third group of organs, as I have arranged them, are the first essential processes for the completion of all others. If secretion is defective, digestion is abnormal; if digestion is abnormal, absorption is defective or material defective for assimilation is absorbed; if absorption is abnormal assimilation is defective. Assimilation being defective, or imperfectly assimilated material passing into the circulation, the organs of excretion are the first to suffer, their function being to eliminate effete or morbid material; but unassimilable material cannot be eliminated by these means without working injury to the organs of excretion. For example, if an excess of amyloid food is taken more than can be transformed by the assimilative process of the liver it passes into the circulation of the blood and finds its way out through the kidneys, as the organs of elimination, and being a crude, unassimilable material it acts as an irritant to kidneys as in diabetes. The disease of the kidneys is secondary. Again the blood making process being defective the blood is ill adapted for its function as the chief element of nutrition. With such a condition nutrition is impaired in the passive tissues of the first group, also the nutrition and function in the active organs of the second, also the organs of excretion of the third group. May not many of the diseasss of the lungs find an explanation by this reasoning? Under such conditions there is in each group obviously a merging of physiological processes into pathological. It is hardly necessary to observe that the pathological changes are always slow; that no disease occurs suddenly, but there has been a gradual lapse of the normal into the abnormal. From this it is appreciable also that disturbances in the first and second groups cannot be corrected except as we look back to the third group and there seek to correct the beginnings of disturbances? Is not every experienced physician conscious that we are unable by known remedies to change directly or continuously heart action, muscular power or nerve force or any of the functions of the second group of organs, much less the tissues of the first group? The third group of organs we have special power to control, assist or modify. Secretion is a function which may be markedly changed by remedies. The whole complex process of digestion depends upon ferments secured by secretion. Disturbed secretion is followed by disturbed digestion which is the first essential condition of health. The glandular organs of this group are of all others prone to disturbances and the most great and serious of all diseases are attributable to defects in the organs of this class.

When we consider the complexity of the process and the variety of food taken under the enticement of appetite, is it strange that most diseases are to be referred back to the digestive group for the origin of disease? Besides it is our province to guide the selection of appropriate food, both for digestion and for the wants of the organism in its varying conditions of exercise. Food may become wholesome for the wants of the system or from some defect in quality for digestion, or excessive in quantity become the rankest poison. I am impressed with the idea that if I could adjust the food to the wants of all, and appropriately guide their exercise, I could by such means remove a large portion of the sickness of the world. Other organs that are notably under the care of the physician are the organs of excretion, also arranged in our third group. The elimination of effete or morbid material we are in a very marked degree able to influence and control. Indeed, every physician finds his largest duty to consist in supplying pure air for the eliminating process of respiration, correctives for the disturbed secretion, and excretion cathartics for clearing the digestive canal, diuretics for the eliminative functions of the kidneys, diaphoretics for the respiratory function of the skin.

It is observed that in all those therapeutic matters we are dealing with the third group of organs in our schedule, and in all these means our skill consists largely in appropriately controlling those functions which are essential for the right state of blood. Those who have had experience in the practice of medicine are conscious that they are unable in a single case to select a remedy which has specific virtues for the cure of any normal disease. They know that all means must be directed to the blood-making and blood-purifying processes, and through the blood to nerve and function of the part affected. They further learn the futility of local agencies to cure idiopathic diseases, as linaments for rheumatism, local applications for diphtheria, erysipelas, or any of the diseases of internal organs. Local means have their place as efficient agents, but the treatment must look back to the conditions that control nutrition. Who can reasonably expect to cure tubercle of the lung or any part by local applications, cancer by excision alone, a specific ulcer by local applications? Are we not able at this stage of our knowledge of physiology to detect the cause of disease as always due to some disturbing agent of nutrition which has definite conditions? With such a view of the art of medicine we may see how contemptible any restricted pathy is which proposes to guide to the cure of disease except as it looks to the correction of physiological disturbances. I am aware that the standing problem to-day for the physician as it has been in all ages is the cause of disease. In answering this question external and internal agencies have been named and their influence vaguely defined. Is it not appreciable that most causes of disease must act to disturb the functions of one or more of the organs of the third group except, perhaps in a few instances where poisons and parasites are distinctly traced? In this line of inquiry if we are met by those who accept the parasitic theory, which is that diseases are the result of microörganisms in the form of bacteria I reply that as yet we have been unable, except in a very limited way, to establish causation from germs or to find any specific agent as an antidote to any of the so-called specific diseases, and in my judgment we need not expect it. Further, I must call attention to the power of resistance in the body, against such infection. It has been fully shown that it is able to resist the infection from disease germs when it is in its normal standard of health.

Mitchenkoff has shown that by a process known as phagocytosis or cell devouring cell, the assimilating power in the blood is sufficient to cope with the lower form of cell life. Bouchard and others have observed the destruction of bacilli by the spleen and their elimination by the kidneys. Buchner and Lubarsch have shown the bactericidal power of blood serum. The liver is also shown to have a destructive power over each organism, and thus guard the system from these sources of disturbance.

If in full health, the antagonism between the normal tissues of the body and disease germs has been shown to be a rational means of defense, these agencies we should wisely guard, rather than that all of the attention should be given to exclude germs from the body. This line of reasoning regarding the antecedents of disease is the outcome of a desire to see adopted by the profession some universally accepted principles on which the practice of medicine may rest as a true art. If clear appreciable principles are established which none can gainsay we have the elements of a true science. The art must, as in all arts, rest upon the judgment of the one practicing it. When such reasoning prevails there can be no place for any of the conflicting theories; there can be no allopathic, homœopathic, hydropathic, uropathic, or any other of the various schisms in medicine. Our practice would then be spoken of and given the confidence due to a rational profession, because all the methods of treatment would be referable to the primary organic disturbance rather than to vague and ever varying symptoms. Inasmuch as we deal with natural phenomena which are always uniform, except in varying conditions we have the elements of as true a science as chemistry, astronomy or physics. The art, to be sure as all other arts, must rest upon the varied and conflicting judgment of those attempting to apply it. With the principles of a true science established, our profession will be glorified because it reaches out and grasps the forces of the Eternal, which tends in the constant changes to conserve human life for a higher end.

AMPUTATIONS IN THE LIGHT OF MECHANICAL SCIENCE.

Read in the Section of Surgery and Anatomy at the Forty-third annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY STEWART LEROY McCURDY, M.D.,
OF DENNISON, OHIO.
Professor of Orthopædic and Clinical Surgery, Ohio Medical University, Columbus, Ohio; Lecturer on Topographical Anatomy and Landmarks, Western Pennsylvania Medical College, Pittsburgh, Pa.; Surgeon, P., C., C. & St. L. Ry. Co.

Dr. Oscar H. Allis, in his paper before the Pennsylvania State Medical Society, June 4, 1891, said: "Don't amputate through the joint; go above or below it." Such a statement by a surgeon of such thoughtfulness and eminence must necessarily carry with it a vast majority of men who amputate, but who allow other men to do their thinking. No one, of course, would for a moment suspect Dr. Allis of making such a statement unless he believed it, and such a conclusion could only be the result of a thorough investigation of the prothegenetic as well as of the mechanical phases of the question.

After having made a study of the matter for the past number of years, I am compelled to make the statement that joint amputations afford the best stumps, and no surgeon is justified in going three inches above the ankle and knee, as the limb maker, Truax, suggests when a disarticulation can be made. Why should three inches of a human extremity be sacrificed because of lack of ingenuity on the part of the mechanic? No; but rather compel the mechanic to fit the stumps you send to him.

There are many reasons why the natural articular surface of a bone covered with abundant soft tissue makes a more durable stump than one formed by a cut through the shaft of a bone. Nothing is more natural than that dealers should, and do, advertise the goods they have for sale, and if he can make a leg that will fit a joint amputation, he will so advertise and recommend the surgeon to disarticulate; but if he cannot successfully do this, he is sure to advise the surgeon to go far enough above the joint to make room for the machinery of his limb. Is this merciful or right in any sense? Yes, it is right unless it is possible to adjust an artificial limb to joint amputation, but it is radically wrong if such limbs can be made and proven more durable and comfortable to the wearer. Dr. Mordecai Price, of Philadelphia, said: "If he had to have an *amputation* below the knee, he would prosecute a man that would give him a stump of more than four or five inches." While it is undoubtedly unwise to go nearer than three inches, and better six inches above the ankle, when the articulation has to be sacrificed. I am firmly convinced that a Syme's amputation makes the best stump possible, and I may say the most comfortable of all stumps. I am also convinced that a disarticulation at the knee joint furnishes a most admirable stump for the adjustment of an artificial limb, and is much more serviceable than at any point above the joint.

Why then should amputations be made through the joint in preference to points above. 1. The broad articular ends of bones make better stumps than cuts through the shaft.

2. The knob (I may be allowed to call it) formed by the condyles at the knee, and maleoli at the ankle, furnishes points about and above which the socket can be adjusted which prevents the pumping motion so common and so very objectionable when a cone stump is to be fitted.

3. Artificial limb makers can and do make limbs for disarticulations.

As to the first proposition. No one will doubt the advisability of making disarticulations, nor will they recommend the sacrifice of one inch more of human tissue than is absolutely necessary, provided stumps at the joints can be satisfactorily fitted. One maker says: "Amputations at the knee are very favorable and are preferable to any point above." Again, the same maker says in speaking of Syme's amputation: "This amputation leaves a stump that combines the greater number of favorable conditions * * * is better than above or below * * * the end of the stump bears the weight, and the patient can be supplied with a leg that fills the highest possible conditions and at the least cost."

Other quotations might be made, but suffice it to prove that limbs *are* made for disarticulations and are better than above the joints.

In Syme's amputation, I have a patient wearing an adjustable lacing socket limb made by the Pittsburgh Artificial Limb Co., who is a freight conductor, and he can jump on and off trains going as fast as he ever could.

I have a number of letters from men with Syme's amputation wearing limbs, and in no case do I find anything but commendation for the satisfaction they get in wearing their substitute.

Puddlers, railroaders, clerks, and laborers of all description, who are compelled to stand or walk all day, have no complaints to make.

In a Syme's or knee operation, the bearing can be received and divided at the will of the patient between two different points. In case of the ankle by simply slacking the lacing of the socket, the bearing can be thrown on the end of the stump, and by tightening the lacing the weight can be received by the head of the tibia.

In knee amputations, so also can the bearing be shifted from the end of stump at the knee joint or upon the muscles of the thigh as may be the pleasure of the wearer. In either case, the patient learns to all the time divide the weight upon the two points and thus make just half the pressure that would be in a leg or thigh amputation.

Surgeons would hardly question the advisability of doing disarticulations provided they were sure they were giving their patients a stump that could be fitted by the mechanic. Again, who will question the advantage of the broad surface of the condyles covered with synovial membrane cartilage, and the structures nature intended to receive pressure, has over the end of a bone cut through the shaft.

The practice of sawing off the condyles and the maleoli is certainly a misguided step. These knob like ends made by the condyles and the maleoli are of wonderful advantage to the patient. When a conical stump is put into a corresponding socket, there is nothing to hold the leg in the socket but a strap worn over the shoulder· This is all right; but in disarticulations this is unnecessary. From the fact that the condyles and maleoli have a greater diameter than a few inches above these points, the limb maker is able to adjust these points and thus prevent the annoying pumping motion of the stump in the socket.

If the condyles or malleoli have to be removed, then there should be no question as to the advisability of making the cut far enough from the joint to allow room for the machinery of the limb maker. It is also argued that when one-half of a joint is removed a substitute cannot be made and retain the normal relationship of the joint. This is not the case, for I have here a limb that places the joint parallel with the lower end of the femur. These photos show a patient wearing one of these limbs, and as you see in the three positions, the act of a full step is shown, which is evidence that a joint can be substituted and the normal relationship of the joint retained.

I am firmly convinced that artificial limb makers should make their limbs so as to make the bearings upon but four points:

1. The ankle as in Syme's.
2. Below knee, or about the head of the tibia.
3. Knee.
4. Perineum.

By this I mean that a conical stump of soft tissue which draws the skin back over the end of the bone, cannot be as comfortable to the patient as a bearing upon the normal articular ends of the bones, or fixed bony prominences.

In all amputations above the knee, I am sure that the future limb will be made so as to receive the bearing on the *tuber ischii* by the use of the Thomas' ring.

Orthopædic surgeons have long since considered this the only bearing for splints that are to receive the weight of the body.

As to tarsal amputations, I believe the proper thing to do in such cases is to perform your Chopart, or a Hayes, tenotomize the tendo Achilles, and in some way induce anchylosis of the remaining tarsal and tibio-tarsal joints. This, you will say, will throw the patient upon the remaining end of the stump in the act of walking, and thus make a limp. I say no.

Please study the part taken by the ankle joint in making one step. As the foot is thrown forward, the ankle joint is extended, and when the leg is perpendicular the joint is at a right angle to the axis of the leg. As the body is thrown forward, the joint does not go into flexion as might be supposed, but instead the foot retains almost the same relationship to the leg as it did when the body was vertical to it. If this be true, then the act of flexion of the foot is not essential to graceful walking. If you notice, as you throw the body forward, there is a graceful rise of the heel from the surface, and the body's weight is received by the ball of the toe.

In other words, the ankle-joint of an artificial limb plays a very minor part in the act of walking. Dr. Cathcart, of Edinburgh, Scotland, has made a thorough study of this subject, and to his papers I most respectfully refer you.

Truax, in his article upon amputations, says: "See that the end of the bone is well rounded or smoothed at its outer border." This reminds me of the boy in my practice who wanted a brass knob put on the end of the bone in his leg after amputation. Nothing is more absurd, and would tend more to encourage necrosis of the end of the bone.

Surgeons should not only know what limb makers cannot do, but they should also know what they can do; and it is their duty to study the prothetical side of the question as well as the surgical.

The writer would do well to cut into a stump of a dead man and see that nature does the rounding up of the end of the bone, and if the surgeon would dare to assist her, his meddlesomeness would be criminal.

The photos 1, 2 and 3 represent a disarticulation at the knee joint, with the knee in the positions necessary in the act of walking. Cuts 4, 5 and 6 represent a Syme's amputation. The patient is a railroad freight conductor, who runs over trains, and jumps on and off trains at ten miles per hour. This man says the point of bearing is just where he wants it —either on the end of the stump or around the head of the tibia. Cut 1 represents an artificial limb for a Syme's amputation, and cut 2 represents one for a knee joint amputation.

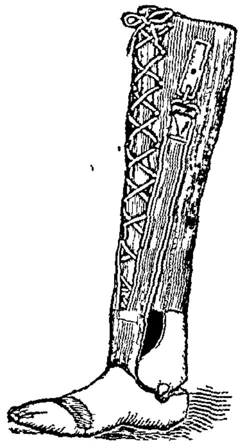

Fig. 1.

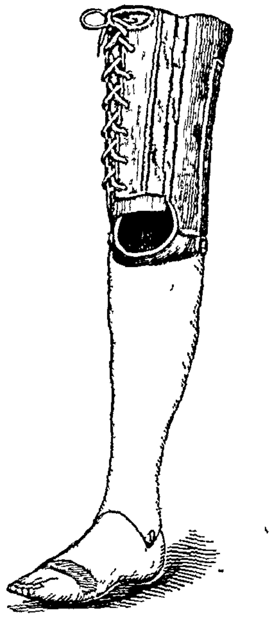

Fig. 2

Dr. Adams inquired as to the use of an artificial foot after Pirogoff's operation.

Dr. McCurdy replied that this operation should not be made at any time, but a good foot can be made for this operation.

Dr. King, of Missouri, disagreed with almost every point made in the paper, basing his objections on considerable experience in railroad surgery. He said that the best artificial limbs were the hollowed out willow limbs, and he considered the cone-shaped stump to be the best. The patient is not expected to walk on the end of the stump. He made it a rule wherever he could to go above the joint.

Dr. Craig, of Pennsylvania, said that he had made a special study of the surgery of the lower extremity, and he agreed with Dr. King. The effect of saving the joint after the ball of the foot is removed is to make the man a permanent cripple. The amputation two inches above the ankle joint gives you no more control than a few inches below the knee, but it exposes a large portion of the limb to friction, and makes a tender limb from the effects of the wrappings round the lower extremity. He believed that every foot to be removed near the ankle joint will be better removed halfway between the ankle and knee.

FORCED RESPIRATION (FELL METHOD), PER FACE MASK AND TRACHEOTOMY IN DIPHTHERIA. REPORT OF CASE.

Read before the Section of Surgery and Anatomy, at the Forty third annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY GEORGE E. FELL, M.D., F.R.M.S.,
OF BUFFALO, N. Y.

The following case is presented with the belief that it has some features of novelty of an interesting character and

1. To illustrate how forced respiration may be of great value in surgical operations associated with conditions of asphyxia.
2. To illustrate its value per face mask and also tracheotomy in cases of membraneous diphtheria and croup.
3. To demonstrate the value of peroxide of hydrogen in asphyxia produced by membraneous exudates in the trachea and bronchi of the lungs.

The history of the case may also prove a valuable lesson to parents with children suffering from throat trouble, and who hesitate to call a physician in time.

A resident of Buffalo, whose family consisted of wife and four children, the eldest a daughter 9 years of age; a son 7 years and 3 months; a daughter 4 years, and an infant son, 2 years of age. The eldest daughter was taken ill with throat troubles and general disturbance of the system. She was quite sick and was taken from school. On the 29th of March, 1892, the eldest son was taken sick, and he like the sister, was treated with home remedies until about 5 A.M., on the Sunday following, June 4, when the father discovered him in a cyanotic condition, breathing with great difficulty, and evidently in great danger. I was called about 8 o'clock in the morning, and arrived at the residence an hour later. On examination I found the four children ill with diphtheria, the exudates being quite clearly marked in the eldest daughter and the son. The son was respiring with great difficulty, and his life was in immediate danger. I informed the father there was only one thing that could be done at that time, and recommended tracheotomy as a means of holding the case, but held out no hope of ultimate recovery of the child. The younger children were also ill, the exudation, however, not so extensive, as the disease had affected them later than the first two. The mother desired the operation to be made. I sent for Dr. Colton, near by, to assist me, but before we were ready to make the operation the lad became unconscious from the cyanosis, and necessarily in a very desperate condition. He was placed upon a table, the initial incision made for the operation of tracheotomy. The blood was purple. No anæsthetic was used, as it was not necessary. A few moments after the first incision was made Dr. Colton called my attention to the fact that the pupils of the eyes were rapidly dilating. I had fortunately prepared my forced respiration apparatus so as to have it ready for immediate use should occasion warrant, and had it not been ready I undoubtedly would have had the experience which frequently comes to some surgeons, of death occurring during the operation. I immediately placed the forced respiration cup upon the face and respired for the little fellow, resulting in changing the blood to a bright scarlet in the wound in the neck and causing the return of auto-respiration. I proceeded with the operation, and found it necessary before I completed it to repeat the respiratory work with the forced respiration apparatus some six or seven times, in some instances having to respire quite a little time before auto-respiration was re-established. This is an unusual and peculiarly interesting fact, associated with the question of interference with respiration through exudates in the respiratory tract, that it is possible, (it may be for a short time only,) to breathe, retain the life of a patient, overcome the influence of the exudate and tone up the system so as to enable auto-respiration to be carried on. I completed the operation and placed the tracheotomy tube in the trachea, and even then found it necessary before consciousness returned to respire some time for the lad. After becoming conscious he breathed with very little trouble for quite a period of time. The general treatment directed was a spray application to the throat and nasal passages of the peroxide of hydrogen, about 30 per cent. aqueous solution. The father was directed to use this occasionally in the wound in the neck if he found it necessary. The afternoon of the day of operation revealed a condition similar to that which existed after the operation in the morning. The boy was moving around the house, although the respirations were at all times more or less labored. At intervals the inner tube of the tracheotomy tube would close up with the exudate and require frequent cleansing. The father stated on my second call that if he had followed my directions to merely spray lightly the wound in the neck, his boy would have died before my return. He found it necessary to place the tube of the spraying apparatus in the opening in the neck, or in the tracheotomy tube, frequently to prevent the cyanotic condition from ensuing, that "the spray appeared to liquify the membrane, or the mattery substance, and cause it to come away in a foamy, frothy state." During the afternoon the condition of patient became worse, the membranes filling up the trachea apparently, so that Dr. Colton, who was present, applied the forced respiration through the tracheotomy tube, again relieving the little patient from the severe dyspnœa which prevailed at the time. Sunday night the case progressed about the same, frequent resort having to be made to the peroxide of hydrogen to enable the little fellow to get along at all. On Monday and Tuesday extensive membraneous casts of the tubes and trachea were coughed up and passed out of the tracheal opening. The boy retained his vigor under the adverse conditions existing until Tuesday afternoon, when the exudate seemed to be increasing and interfered with the respiratory efforts, which condition could not be overcome, even by the forced respiration apparatus, and about eleven o'clock Tuesday evening the patient died from exhaustion and heart failure.

The other patients in the house had upon my arrival been placed upon the common method of treatment which I used in these cases, tincture of chloride of iron, chlorate of potash, bichloride solution and so on internally, with the peroxide of hydrogen spray used every 10 to 15 minutes. While the exudates in their cases were very extensive, there appeared to be no serious invasion of the lung tissue, and they both made a nice recovery without any serious complications.

It was very clearly evidenced in the case of the boy that he would have died before I could possibly have performed the operation of tracheotomy had it not been for the forced respiration apparatus. How many cases of a serious character might be benefited, or have life retained by such work, and tided over the most serious results, cannot be foretold. It is unreasonable to assert that some patients may not recover who are as seriously sick as was this young boy.

Regarding the peroxide of hydrogen, its value was unquestioned. It produced liquefaction of the membranes in the throat; but whether a weaker solution would have proved more satisfactory or not, I am not prepared to state. As mentioned, the solution was about 33 per cent., and this apparently produced no uncomfortable effect when sprayed directly into the tracheal wound. This treatment appeared grateful to the patient in his distress, as also did the forced respiration application when it was made. In fact he eagerly requested that it be utilized later in the case, as it had relieved him once or twice. But, of course, the difficulty was in the prevention of formation of the exudates, which ultimately prevented the respiratory process from being carried on, weakening the patient so that the heart succumbed to the strain put upon it. I think there is no question from the result of the other cases that had this boy been placed in time upon the treatment to which the other children were subjected he might have recovered.

This paper is presented to this Section on account of its bearing upon an operation the surgeon must frequently perform, and if through means of this character the surgeon may be prevented from experiencing that most unenviable notoriety of losing a case during an operation it will be worth the time expended.

ADVANCES IN ASEPTIC SURGERY.

Read in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY FRANK J. THORNBURY, M.D.,

LATE SENIOR RESIDENT PHYSICIAN, CINCINNATI HOSPITAL, CINCINNATI, O.; DEMONSTRATOR OF BACTERIOLOGY, MEDICAL DEPARTMENT UNIVERSITY OF BUFFALO.

I desire to precede the reading of this paper by the statement that much of what I have to say is the product of work recently done in the von Bergmann Clinic, at Berlin.

Many of the ideas and facts are comprised in Schimmelbusche's "Aseptische Wound Behandlung," recently published to formulate in no limited amount of original work, done by von Bergmann's corps and other German investigators.

Having been assigned the English translation of this book, I take the privilege of utilizing some of its contents in this paper, which may serve in a measure as an introduction to the translated volume, which I hope in a short time to have completed.

In considering the subject of the advances in this department of our science, it seems very appropriate to review for a moment the past state of events, that we may be better able to draw the necessary deductions and convince ourselves of the extent of the progress.

We will not go back to the time in which deficiency of anatomical and physiological learning, as well as incompetency in technique, impeded the progress of surgery—but rather refer to a later era of uncertainty in the results seemingly dependent upon some grave mysterious influence which pervaded the field of surgery, and baffled the operator's most earnest efforts.

I refer to the time when the subject of wounds and fever were inseparable; the time when healing without inflammation was unknown, and wound suppuration appeared as the *natural* reaction of the injured organism.

This was the time when Pirogoff wrote that "all efforts of the physician and surrounding circumstance were of no avail, and that the results of an operation are dependent entirely upon fate."

Suppuration, purulent œdema, tetanus, gangrene and erysipelas were called the "scourges of surgery." They followed the operator step and pace, defeating all his efforts.

"Eighty per cent. of all wounds are complicated by gangrene," wrote Lindpaintner from Nussbaum's clinic, in Munich. Erysipelas was of such common occurrence in association with wounds, that men came to regard it as almost a natural complication.

It was made an established rule never to suture scalp wounds, on account of fear that pus would accumulate.

Healing by primary union was almost unknown, and suturing had at most the result of causing retention and accumulation of the secretions and favoring the development of erysipelas. In one report of seventeen amputations, eleven died of pyæmia alone.

A compound fracture seldom occurred which was not either at once amputated, or else the patient died soon as the result of intercurrent gangrene, purulent infection or septicæmia.

The mortality of compound fractures in Volkmann's clinic at Halle for a number of years was 40 per cent., and during 1871 and 1872 pyæmia and erysipelas became so frequent as to necessitate the clinic being closed.

How different it is to-day. The hospitals which twenty years ago numbered gangrene among their most frequent and disastrous complications of wounds, now never present a case for the observation of the student, and the majority of the younger surgeons scarcely know this disease.

The gravest operations now run a favorable course. "Fate" and "mishap" are terms no longer permissible. For the occurrence of suppuration the operator is directly accountable. The future of the patient rests in *his* hands.

We operate in youth and in the aged with the same assurance of a favorable result as that entertained in the robust adult of middle years. The abdomen and the cranium are opened without hesitation, and the visceral contents palpated or incised. We no longer believe that in a carcinomatous or tubercular patient a fresh wound is going to heal other than it would in a healthy individual. The theory of a *diathesis* predisposing to wound inflammation is a thing of the past.

For this enormous transition in surgical science, we are indebted to the illumination of the dark cloud suspended for so long a time over wound infection—to the revelation that in *living microörganisms* rests the danger. If the methods originally used were those now employed in combating the mighty enemy, then there would shine in more *brilliant light* the name of him who first showed us the way to progress—that of Sir John Lister.

But to Hunter belongs the original observation that subcutaneous wounds and simple fractures are unattended by suppuration; Lister comes *later* with the announcement that germs are the cause of infection, but claims that the infection takes place through the atmosphere. Elaborate "antiseptic" spray arrangements were accordingly for a time in vogue. Later investigations, however, proved that *the air* is rarely the medium of infection, that the natural *habitat* of organisms is *organic material* on the earth and elsewhere. Only as *dry dust* do germs get into the atmosphere. From moist surfaces they cannot arise.

The principal circumstances under which bacteria sidered the cone-shaped stump to be the best. The patient is not expected to walk on the end of the stump. He made it a rule wherever he could to go above the joint.

Dr. Craig, of Pennsylvania, said that he had made a special study of the surgery of the lower extremity, and he agreed with Dr. King. The effect of saving the joint after the ball of the foot is removed is to make the man a permanent cripple. The amputation two inches above the ankle joint gives you no more control than a few inches below the knee, but it exposes a large portion of the limb to friction, and makes a tender limb from the effects of the wrappings round the lower extremity. He believed that every foot to be removed near the ankle joint will be better removed halfway between the ankle and knee.

FORCED RESPIRATION (FELL METHOD), PER FACE MASK AND TRACHEOTOMY IN DIPHTHERIA. REPORT OF CASE.

Read before the Section of Surgery and Anatomy, at the Forty third annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY GEORGE E. FELL, M.D., F.R.M.S.,
OF BUFFALO, N. Y.

The following case is presented with the belief that it has some features of novelty of an interesting character and

1. To illustrate how forced respiration may be of great value in surgical operations associated with conditions of asphyxia.
2. To illustrate its value per face mask and also tracheotomy in cases of membraneous diphtheria and croup.
3. To demonstrate the value of peroxide of hydrogen in asphyxia produced by membraneous exudates in the trachea and bronchi of the lungs.

The history of the case may also prove a valuable lesson to parents with children suffering from throat trouble, and who hesitate to call a physician in time.

A resident of Buffalo, whose family consisted of wife and four children, the eldest a daughter 9 years of age; a son 7 years and 3 months; a daughter 4 years, and an infant son, 2 years of age. The eldest daughter was taken ill with throat troubles and general disturbance of the system. She was quite sick and was taken from school. On the 29th of March, 1892, the eldest son was taken sick, and he like the sister, was treated with home remedies until about 5 A.M., on the Sunday following, June 4, when the father discovered him in a cyanotic condition, breathing with great difficulty, and evidently in great danger. I was called about 8 o'clock in the morning, and arrived at the residence an hour later. On examination I found the four children ill with diphtheria, the exudates being quite clearly marked in the eldest daughter and the son. The son was respiring with great difficulty, and his life was in immediate danger. I informed the father there was only one thing that could be done at that time, and recommended tracheotomy as a means of holding the case, but held out no hope of ultimate recovery of the child. The younger children were also ill, the exudation, however, not so extensive, as the disease had affected them later than the first two. The mother desired the operation to be made. I sent for Dr. Colton, near by, to assist me, but before we were ready to make the operation the lad became unconscious from the cyanosis, and necessarily in a very desperate condition. He was placed upon a table, the initial incision made for the operation of tracheotomy. The blood was purple. No anæsthetic was used, as it was not necessary. A few moments after the first incision was made Dr. Colton called my attention to the fact that the pupils of the eyes were rapidly dilating. I had fortunately prepared my forced respiration apparatus so as to have it ready for immediate use should occasion warrant, and had it not been ready I undoubtedly would have had the experience which frequently comes to some surgeons, of death occurring during the operation. I immediately placed the forced respiration cup upon the face and respired for the little fellow, resulting in changing the blood to a bright scarlet in the wound in the neck and causing the return of auto-respiration. I proceeded with the operation, and found it necessary before I completed it to repeat the respiratory work with the forced respiration apparatus some six or seven times, in some instances having to respire quite a little time before auto-respiration was re-established. This is an unusual and peculiarly interesting fact, associated with the question of interference with respiration through exudates in the respiratory tract, that it is possible, (it may be for a short time only,) to breathe, retain the life of a patient, overcome the influence of the exudate and tone up the system so as to enable auto-respiration to be carried on. I completed the operation and placed the tracheotomy tube in the trachea, and even then found it necessary before consciousness returned to respire some time for the lad. After becoming conscious he breathed with very little trouble for quite a period of time. The general treatment directed was a spray application to the throat and nasal passages of the peroxide of hydrogen, about 30 per cent. aqueous solution. The father was directed to use this occasionally in the wound in the neck if he found it necessary. The afternoon of the day of operation revealed a condition similar to that which existed after the operation in the morning. The boy was moving around the house, although the respirations were at all times more or less labored. At intervals the inner tube of the tracheotomy tube would close up with the exudate and require frequent cleansing. The father stated on my second call that if he had followed my directions to merely spray lightly the wound in the neck, his boy would have died before my return. He found it necessary to place the tube of the spraying apparatus in the opening in the neck, or in the tracheotomy tube, frequently to prevent the cyanotic condition from ensuing, that "the spray appeared to liquify the membrane, or the mattery substance, and cause it to come away in a foamy, frothy state." During the afternoon the condition of patient became worse, the membranes filling up the trachea apparently, so that Dr. Colton, who was present, applied the forced respiration through the tracheotomy tube, again relieving the little patient from the severe dyspnœa which prevailed at the time. Sunday night the case progressed about the same, frequent resort having to be made to the peroxide of hydrogen to enable the little fellow to get along at all. On Monday and Tuesday extensive membraneous casts of the tubes and trachea were coughed up and passed out of the tracheal opening. The boy retained his vigor under the adverse conditions existing until Tuesday afternoon, when the exudate seemed to be increasing and interfered with the respiratory efforts, which condition could not be overcome, even by the forced respiration apparatus, and about eleven o'clock Tuesday evening the patient died from exhaustion and heart failure.

The other patients in the house had upon my arrival been placed upon the common method of treatment which I used in these cases, tincture of chloride of iron, chlorate of potash, bichloride solution and so on internally, with the peroxide of hydrogen spray used every 10 to 15 minutes. While the exudates in their cases were very extensive, there appeared to be no serious invasion of the lung tissue, and they both made a nice recovery without any serious complications.

It was very clearly evidenced in the case of the boy that he would have died before I could possibly have performed the operation of tracheotomy had it not been for the forced respiration apparatus. How many cases of a serious character might be benefited, or have life retained by such work, and tided over the most serious results, cannot be foretold. It is unreasonable to assert that some patients may not recover who are as seriously sick as was this young boy.

Regarding the peroxide of hydrogen, its value was unquestioned. It produced liquefaction of the membranes in the throat; but whether a weaker solution would have proved more satisfactory or not, I am not prepared to state. As mentioned, the solution was about 33 per cent., and this apparently produced no uncomfortable effect when sprayed directly into the tracheal wound. This treatment appeared grateful to the patient in his distress, as also did the forced respiration application when it was made. In fact he eagerly requested that it be utilized later in the case, as it had relieved him once or twice. But, of course, the difficulty was in the prevention of formation of the exudates, which ultimately prevented the respiratory process from being carried on, weakening the patient so that the heart succumbed to the strain put upon it. I think there is no question from the result of the other cases that had this boy been placed in time upon the treatment to which the other children were subjected he might have recovered.

This paper is presented to this Section on account of its bearing upon an operation the surgeon must frequently perform, and if through means of this character the surgeon may be prevented from experiencing that most unenviable notoriety of losing a case during an operation it will be worth the time expended.

ADVANCES IN ASEPTIC SURGERY.

Read in the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY FRANK J. THORNBURY, M.D.,
LATE SENIOR RESIDENT PHYSICIAN, CINCINNATI HOSPITAL, CINCINNATI, O.; DEMONSTRATOR OF BACTERIOLOGY, MEDICAL DEPARTMENT UNIVERSITY OF BUFFALO.

I desire to precede the reading of this paper by the statement that much of what I have to say is the product of work recently done in the von Bergmann Clinic, at Berlin.

Many of the ideas and facts are comprised in Schimmelbusche's "Aseptische Wound Behandlung," recently published to formulate in no limited amount of original work, done by von Bergmann's corps and other German investigators.

Having been assigned the English translation of this book, I take the privilege of utilizing some of its contents in this paper, which may serve in a measure as an introduction to the translated volume, which I hope in a short time to have completed.

In considering the subject of the advances in this department of our science, it seems very appropriate to review for a moment the past state of events, that we may be better able to draw the necessary deductions and convince ourselves of the extent of the progress.

We will not go back to the time in which deficiency of anatomical and physiological learning, as well as incompetency, in technique, impeded the progress of surgery—but rather refer to a later era of uncertainty in the results seemingly dependent upon some grave mysterious influence which pervaded the field of surgery, and baffled the operator's most earnest efforts.

I refer to the time when the subject of wounds and fever were inseparable; the time when healing without inflammation was unknown, and wound suppuration appeared as the *natural* reaction of the injured organism.

This was the time when Pirogoff wrote that "all efforts of the physician and surrounding circumstance were *of no avail*, and that the results of an operation are dependent entirely upon fate."

Suppuration, purulent œdema, tetanus, gangrene and erysipelas were called the "scourges of surgery." They followed the operator step and pace, defeating all his efforts.

"Eighty per cent. of all wounds are complicated by gangrene," wrote Lindpaintner from Nussbaum's clinic, in Munich. Erysipelas was of such common occurrence in association with wounds, that men came to regard it as almost a natural complication.

It was made an established rule never to suture scalp wounds, on account of fear that pus would accumulate.

Healing by primary union was almost unknown, and suturing had at most the result of causing retention and accumulation of the secretions and favoring the development of erysipelas. In one report of seventeen amputations, eleven died of pyæmia alone.

A compound fracture seldom occurred which was not either at once amputated, or else the patient died soon as the result of intercurrent gangrene, purulent infection or septicæmia.

The mortality of compound fractures in Volkmann's clinic at Halle for a number of years was 40 per cent., and during 1871 and 1872 pyæmia and erysipelas became so frequent as to necessitate the clinic being closed.

How different it is to-day. The hospitals which twenty years ago numbered gangrene among their most frequent and disastrous complications of wounds, now never present a case for the observation of the student, and the majority of the younger surgeons scarcely know this disease.

The gravest operations now run a favorable course. "Fate" and "mishap" are terms no longer permissible. For the occurrence of suppuration the operator is directly accountable. The future of the patient rests in *his* hands.

We operate in youth and in the aged with the same assurance of a favorable result as that entertained in the robust adult of middle years. The abdomen and the cranium are opened without hesitation, and the visceral contents palpated or incised. We no longer believe that in a carcinomatous or tubercular patient a fresh wound is *going to heal other than it* would in a healthy individual. The theory of a *diathesis* predisposing to wound inflammation is a thing of the past.

For this enormous transition in surgical science, we are indebted to the illumination of the dark cloud suspended for so long a time over wound infection—to the revelation that in *living microörganisms* rests the danger. If the methods originally used were those now employed in combating the mighty enemy, then there would shine in more *brilliant light* the name of him who first showed us the way to progress—that of Sir John Lister.

But to Hunter belongs the original observation that subcutaneous wounds and simple fractures are unattended by suppuration; Lister comes *later* with the announcement that germs are the cause of infection, but claims that the infection takes place through the atmosphere. Elaborate "antiseptic" spray arrangements were accordingly for a time in vogue. Later investigations, however, proved that *the air* is rarely the medium of infection, that the natural *habitat* of organisms is *organic material* on the earth and elsewhere. Only as *dry dust* do germs get into the atmosphere. From moist surfaces they cannot arise.

The principal circumstances under which bacteria are found in the air are, first, in winds and other forms of violent agitation of the atmosphere; secondly, in rooms after sweeping, and in enclosed compartments with defective ventilation and bad hygenic surroundings; and finally, they are present in the air of densely populated cities.

Here we may find bacilli and micrococci, in numbers varying from a few to many thousands per cb. cm.: while in the free open air, principally moles and the spores are present in limited numbers.

In mid-ocean atmosphere there are no germs present. Of this fact I convinced myself in a recent transatlantic voyage.

While still in the Shelda River and English Channel, and again on nearing Sandy Hook and sailing into New York Bay, occasional isolated colonies developed on exposed agar plates. In mid-ocean, between 5 and 40 degrees W. longitude. no germs at all were present in the atmosphere. This was also true of the air blowing from the iceberged Newfoundland banks. In the staterooms and in the first and second cabins of the steamer, on the other hand, many bacteria were found on short exposures, especially in the halls after dining hours.

In the steerage, where there were 1,100 emigrants packed together in filth, many thousand bacilli and micrococci came to luxuriant development on agar plates and in the large gelatine tubes.

The colonies in 3 to 5 liter aspirations were numerable only by Esmarch's graduated scale. *Many of* the bacteria thus isolated presented virulent characteristics as regards growth and development. I have made some inoculation experiments, but as these are not yet completed, I cannot now make further definite report.

The reverse of dryness, diffused daylight and sunshine, nature's anti-microbic resources, are all present in close packed compartments, like the rooms of a tenement house and the steerage, and hence the multiplicity of forms of infectious bacteria here present.

The recent incubation of a typhus fever epidemic on an emigrant steamer reaching New York quarantine, may easily be accounted for.

Naegali demonstrated theoretically, as long ago as 1870, that only through currents of air are germs taken up from their usual *habitat*—organic material, and that never do they rise from *solutions*, however rich in bacteria. In this fact we have a valuable practical suggestion as to the importance of the spray in diphtheria and other local infectious diseases, and also the aseptic efficiency of washing down the walls, spraying the atmosphere and sprinkling the floor of the clinic previous to operation—a practice executed daily by Leopold.

Moist air never contains anything like the number of germs which are present in a dry moving atmosphere. This factor, second to the absence of the prolific source, organic material, accounts for there not being any germs in the sea air and in the air of mountain tops. *They are held down, in the one instance* by the sea water, in the other by the snow covering the mountain peaks.

As evidence of the effect which stirring up the air has on its bacterial contents, Hesse found that the 3,000 germs to the cb. cm. present ordinarily in a school room, increased to 20,000 during the sessions, and to 40,000 when the pupils were marching out of the room.

Petri found the air of crowded stables to contain 30,000 bacilli and 7,400 mold spores to the cb. cm.

Very extensive has been the belief, both in medicine and with the laity, that the exhaled breath may convey infection.

But Tyndall demonstrated that the air expired almost never contains germs. Strauss found that in bacteria-enriched atmosphere, in hospital wards, of 600 germs inhaled, but very few were exhaled.

Cadeac and Malet conducted the expired breath of sheep, affected with anthrax and chicken-pox, through troughs ½ to 3 meters long, having healthy animals inhale it; but notwithstanding repeated efforts, in no instance could the non-affected animals, placed at different distances along the trough, be made per inhalation to contract the disease.

The lungs do not give up germs from their moist alveolar surfaces. On the contrary, they filter out the microbes and purify the air bacteriologically, as well as with reference to carbon dioxide.

Only through the sputum or expectorated tissue particles, or through mucus secretion, can disease be communicated from the respiratory apparatus. As Strauss states, the respiratory function must tend to diminish the bacteria in an overcrowded auditorium. It may be a source of gratification to a lecturer to know that each listener brings with him a filter in the functions of his respiratory apparatus. With every breath about 500 cb. cm. of air is freed of its bacteria.

The more our knowledge of bacteriology has been extended, the less have become our fears of infection taking place through the air, and relatively unimportant is such possibility as compared with the dangers of direct contact of infectious materials.

Supposing a cubic meter of air does contain 1,000 to 20,000 germs, what is this, as compared with the half million to the cb. cm. present in river water, or the million or more contained in a single drop of pus or other highly contaminated fluid?

Repeated examinations in the von Bergmann clinic have shown that the number of germs which precipitate over an area of a quarter of a decimeter in thirty minutes of time, during the clinic hour, was at most but sixty to seventy, and as for pathogenic bacteria ever being present, it was an extreme rarity. Practical experience has long since demonstrated that the air is comparatively harmless, as regards its capability of infecting wounds.

It is the infection through contact which most engages our attention. To review the wound-infecting germs, we have first of all the erysipelas streptococcus of Fehleisen; second, the Nicolarer, Rosenbach, Kitasato, anarobic, tetanus bacillus, with its numerous ptomaines, "tetanin," "tetantoxin," "hydrochlorin" and "spasmotoxin," isolated by Brieger, capable of producing typical tetanic convulsions when inoculated even in infinitely small doses. Then we have the familiar staphylococcus pyogenes aureus, citrius and albus *of ordinary suppuration, furuncle*, carbuncle, paronychia, phlegmon, and nearly all the cases of *pyæmia*.

Fourth—the frequent cause of specially severe suppurative processes—the staphylococcus pyogenes, whose form and morphological characteristics so closely simulate the Fehleisen streptococcus of erysipelas *that many bacteriologists claim* them to be identical, differing only in location, representing a deep-seated and especially virulent form of the same disease.

Less frequent, as pus formers, are other cocci, for instance the micrococcus pyogenes tenuis (Rosenbach)

Very common, in excessive wound secretion, is the much discussed bacillus pyocyanus, or blue pus former. Anthrax, tubercle, glanders and diphtheria bacilli have for a long time been classed with those germs whose biological relations we thoroughly well understand. The causes of most forms of peritonitis, especially the perforative, have recently been found to be dependent upon two germs, whose *habitat* is the small intestine. They are the bacillus coli communis and bacterium lectis ærogenes.

We have also a special germ for septicæmia and severe necrotic processes. There remains now only one of the wound complications whose cause we have not discovered, namely: gangrene, the former scourge of hospitals and army life, but now swept out of existence; not even affording an occasional case for necessary bacteriological observation. We have in the subsidence of this disease a most brilliant triumph for aseptic surgery.

Finally, we have isolated the varied, destructive and often epidemic animal septicæmias, namely: the swine plague, wild game plague, chicken cholera, rabbit septicæmia and ferret plague, all of which present marked similarities, but differentiate themselves in the results of inoculation in the different animals.

To make practical application of the finding of germs, the first in surgical importance to us, is their presence on the surface of the body. Eberth, in 1875, first discovered that all imaginable forms of bacteria are found in normal perspiration.

We have on the skin all the factors conducive to the development of bacteria. First, there is the uniform temperature; second, moisture afforded by the excretion of the glands; and third, a culture medium is formed by the decomposed epidermis. The axillary space, interdigital folds and the hairy scalp, seem to be fertile soil for every possible form of microbe life. Miller found several varieties in the mouth.

We have here the, 1, lipothrix innominata; 2, bacillus bucallis maximus; 3, leptothrix bucallis maximus; 4, jodoccus vaginatus; 5, spirillum sputegnum; 6, spirochæte dentium; and four ordinary pathogenic bacteria, viz.: 1, micrococcus gingivæ pyogenes; 2, bacterium gingivæ pyogenes; 3, bacillis dentatis virides; and 4, bacillus pulpæ pyogenes.

Throughout the alimentary canal, in the female genital tract to the os internum, in the male urethra, in the upper respiratory passages, in the conjunctival secretion, and in the cerumen of the auditory canal, masses of bacteria are found. With the occurrence of a slight catarrhal process, the germs at once multiply with striking rapidity and number millions in a short time.

The cleansing of the surface of the body and the removal of the promiscuous forms of bacteria, many of which are pathogenic, constitutes the first requirement in asepsis. Not merely the skin of the patient in the region to be operated upon must be cleansed, but the still more infectious source, the hands of the surgeon. This disinfection is not an easy matter. The fat and dirt filling up the pores and epidermal folds in the skin contain a substratum rich in bacteria. A transitory submersion in the strongest sublimate solution has little influence. The fluid rolls in drops off the fat, glistening skin, without even thoroughly moistening it. In the skin and under the nails, the number of the bacteria remain practically unaltered after such a "*would-be disinfection.*"

Of course the absolute demand for a most careful cleansing of the surface needs no further argument. The method to be used may be formulated as follows: First, washing with soap and water as hot as can be borne, for one minute. Second, rubbing and drying the surface with sterile gauze. Third, one minute application of 80 per cent alcohol. Fourth, washing with sublimate solution. Ether in addition may be used where there is an unusual amount of dirt to be removed. The razor is most valuable over parts even not especially hairy, as it removes the superficial epidermal hairs, in which the bacteria aggregate. It cannot be applied so extensively to the scalp, but even here, the area should be shaved from 3 to 5 cm. from the margin of the wound.

An aseptic cleansing of the mucous membranes is less easily effected. Steffeek found that irrigation of the vagina with a liter solution 1 to 1,000 bichloride had not the slightest influence in reducing the number of bacteria. A stronger solution would of course be dangerous. Erosions and acute catarrh, or a general intoxication, might result from absorption. A mechanical cleansing of the rectal, vaginal and oral mucous membrane is to some extent practicable, by means of tepid sterilized water and gauze, or a physiological solution of common salt. The stomach is also permissible of free irrigation. Operations in emergency upon the intestine should be preceded by a preparatory course of catharsis.

All the articles and materials used in the disinfection of the surfaces cutaneous and mucous, must, of course, *themselves* be aseptic. The alcohol, ether and turpentine oil, only by careful handling are kept free from bacteria.

Eiselsberg showed in 1887, that *soap* may be very richly impregnated with microörganisms, and only that which has been boiled in the process of its manufacture should be used.

Most danger of all and the thing to which the least attention has been given are the *nail brushes*, used in removing blood, pus, surface epithelium and all forms of contamination, they naturally become more or less contaminated themselves; being moist, they retain most of the albuminous matter and form a most excellent nidus for germs. Schimmelbusch and Spielhagen in repeated examinations of the nail brushes, in clinics, dissecting rooms and laboratories found in them inestimable myriads of bacteria. That the brushes therefore, merits some attention must be conceded. Brushes in the von Bergmann clinic, are dealt with in the following manner: before being used, they are first, sterilized in steam for 30 minutes; second, they are kept continually *submerged* in $\frac{10}{20}$ corrosive sublimate. Third, after a special contamination, they are placed in very hot and finally in boiling water. In every commode should be placed an especially constructed enamel receptacle in which the brush can be continuously *submerged in corrosive* sublimate. The latter will maintain asepsis by preventing the development of bacteria after the brush has been sterilized in boiling water or steam.

Next in order the instruments themselves, will engage our attention. The impracticability of disinfecting them sufficiently, by means of antiseptic solutions is now clearly proven. The instruments must are found in the air are, first, in winds and other forms of violent agitation of the atmosphere; secondly, in rooms after sweeping, and in enclosed compartments with defective ventilation and bad hygenic surroundings; and finally, they are present in the air of densely populated cities.

Here we may find bacilli and micrococci, in numbers varying from a few to many thousands per cb. cm.: while in the free open air, principally moles and the spores are present in limited numbers.

All the articles and materials used in the disinfection of the surfaces cutaneous and mucous, must, of course, *themselves* be aseptic. The alcohol, ether and turpentine oil, only by careful handling are kept free from bacteria.

Eiselsberg showed in 1887, that *soap* may be very richly impregnated with microörganisms, and only that which has been boiled in the process of its manufacture should be used.

Most danger of all and the thing to which the least attention has been given are the *nail brushes*, used in removing blood, pus, surface epithelium and all forms of contamination, they naturally become more or less contaminated themselves; being moist, they retain most of the albuminous matter and form a most excellent nidus for germs. Schimmelbusch and Spielhagen in repeated examinations of the nail brushes, in clinics, dissecting rooms and laboratories found in them inestimable myriads of bacteria. That the brushes therefore, merits some attention must be conceded. 'Brushes in the von Bergmann clinic, are dealt with in the following manner: before being used, they are first, sterilized in steam for 30 minutes; second, they are kept continually submerged in $\frac{10}{20}$ corrosive sublimate. Third, after a special contamination, they are placed in very hot and finally in boiling water. In every commode should be placed an especially constructed enamel receptacle in which the brush can be continuously submerged in corrosive sublimate. The latter will maintain asepsis by preventing the development of bacteria after the brush has been sterilized in boiling water or steam.

Next in order the *instruments themselves*, will engage our attention. The impracticability of disinfecting them sufficiently, by means of antiseptic solutions is now clearly proven. The instruments must be sterilized and the choice of method lies between hot air, steam and boiling water. Only the latter of these, will we consider. Spores of many bacilli resist hot air at 140° C. for two hours, and steam for forty minutes to one hour. While boiling in soda, insures *absolute death* of even anthrax, in three minutes. A special apparatus devised by Schimmelbusch, for this method of sterilizing instruments, together with other sterilizing apparatuses, will presently be demonstrated.

The especially commendable feature about this german sterilizer, is its economy of time; and if an instrument happens to drop during an operation, and one that cannot be well dispensed with, we are not obliged to wait for 40 minutes, while it is being sterilized. The instrument is at once thrown into the boiling soda, continually provided in the clinic by the above sterilizer, and in three to five minutes it is taken out aseptic.

Special stress should be laid upon the mechanical cleansing of instruments,as well as all things to be rendered aseptic. Pus, blood and masses of fat, the favorite niduses of organisms, must rigidly be dealt with, by washing with water, soap and brush, before they are put into the boiling soda. After use, they should be carefully dried with alcohol and dry sterile gauze. But with this method there is not the liability of rusting which follows dry heat and steam. Further the instruments are not corroded as with carbolic solution and sublimate. Solutions which even applied *concentrated* does not insure asepsis.

In the construction of the instruments, simplicity should not be lost sight of. All ornamentations and unnecessary fixings of every kind, are contra-indicated on grounds of asepsis. The one piece of steel, may enter into the formation of both the blade and handle, or the latter may be detachable. Instruments made of aluminium, lose one-ninth of their weight, by simply boiling for five minutes. Therefore this material is not to be employed.

Next of interest to us, are the *dressings* to be used, the first quality they should possess is the capability of rapid absorption. Second, they should not contain any bacteria. Third, they should work antiseptically in preventing decomposition of the secretions which they absorb.

Not the dressings which absorbs its maximum at once, and then becomes packed, and remains wet, but material which takes up the secretions gradually, as they are produced and dries out by evaporation, form the ideal dressing. *Sterility* the second prerequisite is absolute and applies to anything which is to come in contact with pure fresh wounds. Both Schlange and Löffler, have found factory gauze and bandages to contain many germs. The necessity of sterilizing the dressings, therefore, follows as a natural consequence. Steam in this instance, is the most efficient means at our disposal.

Schimmelbusch has invented an ingenious apparatus, which may be used for the combined purpose of an instrument and dressing sterilizer. The steam which has been generated in the boiling soda, is utilized in a chamber placed above for sterilizing the dressings. This combination answers admirably the requirements of the private practitioner. But for the more extensive usage of hospitals and amphitheatres, a *special* sterilizer for dressings is necessary. Then the Schimmelbusch apparatus recommends itself, or the Arnold steam sterilizer may be used. These, with another sterilizer for water, presently to be referred to, I have through the kindness of Mr. Wilmot Castle, of Rochester, N. Y., been able to place here, on exhibition, and will be pleased to demonstrate them to the gentlemen present.

The third requirement in dressings, is an antiseptic property. The prevention of the development of germs in the secretions of the wound which serves only too well, the purpose of a culture medium, being the indication to be met. I desire here to lay special stress upon the subject of dry dressing, as it is not in accordance with the usual ideas of wound treatment, as practiced by most surgeons. The more our experimental knowledge has been extended, the firmer has been the position gained by *dryness*, as a condition contrary to a germ development.

There is no remedy so harmless, simple and efficacious in preventing changes in the wound secretion, as dryness occurring of itself by evaporation. Moisture is the essential dependence of bacterial life. Dryness, on the other hand, is the germ's greatest enemy. Let the most favorable nutrient of bacteria, *moisture*, be dispensed with and the organisms cease to grow. Let then the absorption and drying out of the blood, pus and wound secretion be provided for, and the development of germs is *prevented*.

We are indebted to the Esmarch school, especially to Neuber, for having placed the importance of dry dressings in their present advanced position. Schlange in the von Bergmann Clinic, demonstrated by exacted bacterical experiments, how prompt dryness works against every form of germ life. Layers of sterile, gauze wire saturated with bullion and the upper surface impregnated with the green pus bacillis, then the gauze was placed in open glass plates; and evaporation and dryness took place, and only a very scanty development of the bacteria became perceptible. A logical consequence, and one exactly in accordance, with organic life development in any form. Moisture is essential to growth. Instead of leaving the plates open, others of the same series were closed and evaporation of the moisture prevented. The pus formers now proliferated with enormous rapidity and soon formed a greenish film over the entire surface of the gauze. This suggests the practical advantage of facilitating to every possible extent, evaporations of the secretions from the wound.

First, the proper dressing material must be selected. Secondly, the evaporation must not be interfered with, by the interlaying of impervious material as oil silk, or gutta percha tissue. The latter, are of no special advantage, they prevent the wound and dressings from drying out, cause retention of the secretions, prohibiting even perspiration from the surface and inducing in the course of a few hours, the development of offensive odors, and very non aseptic conditions.

These facts are exactly in accordance with our laboratory experience as bacteriologists. As soon as the gelatin or agar tubes lose their surface moisture by evaporation, growth of the colonies cease, and the culture is lost. Hence the necessity of our *capping* the tubes, to favor the development of the bacteria—a procedure analogous to the application of impervious silk over wounds.

In the dressing then,we may combine a parasiticide influence, in *dryness*, an agent which will not injure the tissues locally, or cause general disturbance. It is not with bullion or water that we have to deal, in a-wound, but rather with *albuminous* culture material, which decidedly limits the action of chemicals. Further, evaporation of the carbolic and sublimate solutions, takes place, and combinations form reducing the effectual workings of these agents.

In sublimated gauze after a time, only an insignificant trace of the original antiseptic is to be found. The simple *dry treatment* of wounds, then, is the present position of surgical science, and is reinforced on all sides by logic and rational experience and results.

No oiled silk to promote retention of secretions, no chemicals to irritate the wound, no irrigation to carry germs into it, no pus. Only in two instances is anything additional to the simple dry sterile gauze needed. One is in the case of thick tenacious purulent discharge. The other is the tamponing of cavities, and the latter indication is admirably met .in the iodoform dressing. Non-irritating and non-toxic (in reasonable quantity,) it prevents changes in the absorbed secretions. Notwithstanding the repeated attack made upon it, iodoform retains its place as prominently as ever as our most reliable dressing.

In the case of excessive purulent secretion, acetic acid, oxide, or chloride of zinc may be applied to the wound.

Since it has been shown, that raw cat gut is rich in bacteria, and Volkman had two cases of anthrax develop in a wound sutured with sheep ligature in which animal anthrax is common; further, by reason of Koch having demonstrated that antiseptics dissolved in oil, are ineffectual, we are now required by this progress in our science, to put ligatures and catguts also, through a course of sterilization.

Steam for the silk is the best method, and Schimmelbusch has given us a sterilizer consisting of a small box, containing several spools which can be placed in the steam chamber for thirty minutes, then closed and kept for use as desired. The ends of the thread protrude through openings at the side, so that raising the cover and permitting contamination is *obviated.*

With reference to catgut, the various methods employed are first, von Bergmann's ether sublimate and alcohol, McEwen's chromic acid, Lister's carbolic acid method, then Benkisser's Ravardin process of dehydration and deoleation, then disinfecting by hot steam.

Kocher sterilizes the catgut in juniper oil, Brunnes in Xylol. Of these various methods, that employed by von Bergmann is the one to be recommended, and may be briefly formulated as follows: First, the bottle is sterilized for three quarters of an hour in steam. Second is a process of deoleation, by placing the catgut for 24 hours in ether. Third, submersion in alcohol and sublimate of the following proportions: bichloride 10.0, absolute alcohol 800.0, aq. destillata 200.

The hermetically sealed bent tubes of Fowler, containing sterilized catgut, is also an efficient means of preserving this material aseptic.

The subject of wound drainage deserves just a passing notice. Three methods are embraced in the chapter. 1. The simple opening made through the tissues. 2. The use of drainage tubes. 3. The use of materials. capable of capillary attraction. Neuber advances the theory of an absorbable material so the wound can be closed. Trendelenburg and also McEwen used chicken bones, hollowed out. Bundles of catgut is Watson Cheyne's favored method. Then there are the old glass and gun drainage tubes. Probably the latter are the more satisfactory in the greater number of instances. They permit of being sterilized in boiling soda or steam. Five minutes of the former, 15 or 20 of the latter is sufficient to render them reliably aseptic.

They are preserved aseptic in a five per cent. carbolic acid solution, occasionally renewed. For fastening the tube in place, not the ordinary safety pin, but a sterilized silk thread passed with a needle, rendered aseptic, is to be employed.

The principle of capillary attraction can be utilized best in absorbing the discharges and wound secretion by means of the hydrophiline gauze. Absorbing pledgets for use in the operation are best supplied in the same material. Of course the gauze cannot be used but once, but we should not economize in the use of the materials applied direct to the wound but rather in the external dressing. Only gauze *scrupulously sterile* should be applied. Sponges while apt to be a source of danger, cannot absolutely be dispensed with, especially in operations about the mouth, resections of the jaw and in laparotomies. Absorbing so freely pus, blood and all fluids contaminated or not, they are, *a priori* apt to retain and convey infection and permit only with difficulty of being sterilized.

Anthrax spores were found in sponges, after being 14 days submerged in carbolic acid. The ordinary organisms live for eight days. Twenty per cent. of the sponges prepared for use in the Billroth Clinic were found by Friesch to contain bacteria. The method of preparation of the sponges, employed by Schimmelbusch, consists first in washing them thoroughly in hot water, removing carefully all foreign substances. After several rinsings they are boiled for 30 minutes in 1 per cent. soda solution, then preserved in strong corrosive sublimate. Of course they must be enveloped in gauze, so that the fingers will not come in direct contact with what is to find application perhaps in the abdominal cavity. This method can be regarded as *absolute.* Sponges impregnated with pus and anthrax spores did not react to culture efforts after ten minutes in the boiling soda.

For a continuance of this subject in the "Septic Dangers of Hypodermic Injection, Catheterization and Irrigation of Wounds, the reader is refered to a paper by the writer under the above title published in the *Medical and Surgical Times.*

610 Main St., Buffalo, N. Y.

THE COSMETIC SURGERY OF THE NOSE.

Read in the Section of Surgery and Anatomy, at the Forty third annual meeting of the American Medical Association held at Detroit, Mich., June, 1892.

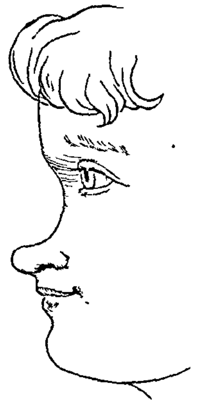
BY JOHN B. ROBERTS, M.D.,

PROFESSOR OF SURGERY IN THE *PHILADELPHIA* POLYCLINIC AND IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA.

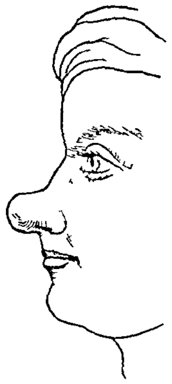
Operative surgery can do so much to relieve disfiguring nasal deformities that perhaps the topic will prove interesting for discussion at this representative meeting. The medical profession fails to fully realize that nearly all undesirable distortions of the nose can be improved or entirely corrected by cosmetic operation. It is, therefore, not astonishing that many persons remain in constant unhappiness because of the consciousness that a congenital or accidental disfigurement is the occasion of impolite stare or impertinent remark.

Operations, often quite trivial, change noses notable for ugliness into organs of symmetrical lines. Such cosmetic improvement naturally makes the patient happier in mind; and not infrequently improves physical health as well, by restoring the normal respiratory and vocal functions of the nasal chambers. Even when more extensive, such operations, if properly performed, carry with them no risk to life. Hæmorrhage of serious kind and violent inflammation are practically unknown; and unseemly scarring does not occur to be an impediment to radical surgical work. Much can be done to the nose, through the nostrils or mouth, without making an incision in the skin of the face. Cuts on the cutaneous surface are inconspicuous, or even invisible, when made in selected spots and with oblique division of the tissues, and when so treated that primary union is secured. Such incisions should be made in the normal lines of the skin, not across them, or should be placed in the situations where shadows, rather than strong lights, usually fall. Careful *asepsis or antisepsis, oblique incision of the skin,* fine catgut sutures and iodoform with collodion as a dressing insure unnoticeable scars, even when the incisions are made in less desirable sites than those just mentioned.

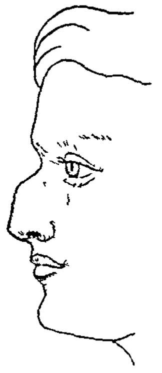
The recognition of tertiary syphilis of the nose and the recollection of its frequency among the educated and refined are requisite qualifications for the successful practice of this branch of general surgery. Many deformities, due to inefficient management of such curable lesions, have come to me for operative treatment. That physicians allow such disfigurements to happen is very astonishing. It should be a rule of practice to give all patients with stationary or chronic ulceration of the interior or exterior of the nose, full doses of mercury and iodide of potassium. The therapeutic test carried on for ten days will usually clear up doubtful cases, if sufficient doses of these drugs are given. A third or a half of a grain of green iodide of mercury taken before meals, and twenty to thirty grains of potassium iodide taken after meals will cure many ulcerated noses. It is the neglect of this active treatment that furnishes the most frightful disfigurements that fall into my hands for cosmetic procedures.



Saddle-back nose.



Tuberous nose.



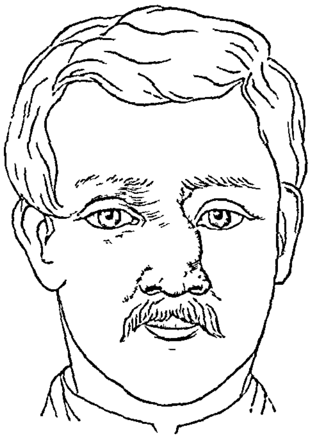
Angular nose.

It is useless to detail fully here the causes which may give rise to nasal *deformity*. Congenital imperfections, such as epicanthus and the flattened and dilated nostril accompanying hare-lip can usually be greatly improved. The Roman nose, the Jewish nose and the nose with an angular prominence on its dorsum can, in many instances, be satisfactorily modified by careful chiseling away of the angular projection of bone and cartilage.

Here a single incision along the edge of the dorsum allows the surgeon to stretch the skin open, so as to apply a sharp chisel to the whole breadth of the nose and shave the bridge into a becoming shape. I have found that the chisel often does best work when used with the beveled side of the cutting edge toward the bone.

Fractures make, of course, all forms of irregularity, and may be accompanied by such blocking up of the nostrils as to require quarrying with chisels and burrs to open the air passages.

I have seen ugly twists given to the cartilaginous nose by what seems to be an interstitial over-growth of the triangular cartilage of the septum. As this cartilage abuts against bone above and below, such over-growth causes marked curves in its outline, which secondarily displaces the cartilaginous portions of the external nose, giving it an ugly twist.

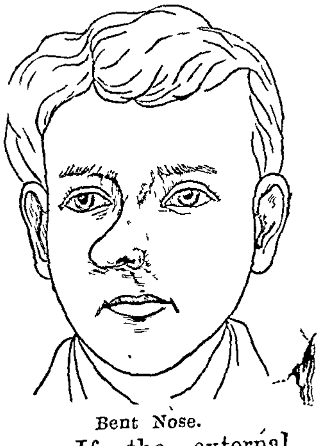


Twisted Nose.

Efficient treatment of this abnormal shape of the organ must include excision of a considerable portion of the septal cartilage. Sometimes, but not always, this may be done by sub-mucous resection.

Tumors involving the tip of the nose can readily be removed by a V-shaped incision; the nasal lobule is afterwards reconstructed by bringing the flaps together in a judicious manner. The fact that the nares are laid open by the incision makes no difference. The wound can be protected from septic infection by thoroughly cleansing the mucous membrane before operation, and plugging with antiseptic gauze after operation.

The improvement in the patient's appearance made by excision of tubercular excresences of the nose due to acne is most astonishing. Yet, many patients go through life with these deformities, never knowing their remediable character. An insignificant operation will cure promptly the horrible and often disgusting disfigurement. Tumors involving the alæ will often require the surgeon to construct a new *ala from* the cheek after excision of the growth.



Bent Nose.

Syphilitic destruction of the bones and cartilages give us the most difficult cases to remedy because of the actual loss of substance. If the external tissues are intact, however, great destruction of the internal parts of the nose may be successfully neutralized. I have satisfactorily used the tissues of the forehead and upper lip for making a bridge and a columella respectively. In a somewhat

Form of Syphilitic Nose.

similar manner I have propped up a sunken bridge in fracture by turning up a flap cut from the septal cartilage and changing its direction. Chiselling loose the nasal bones and pinching them together towards the middle line will elevate the bony dorsum in saddle-back·nose, and by narrowing it at the same time, give it a relative height which will lessen deformity.

After syphilitic ulceration of the internal structures, the ex- rnal soft parts are often drawn into the nasal cavies by cicatricial contraction and respiratory sucon. To elevate and to keep elevated the external ose, so as to restore the nasal projection and facial nformation, is sometimes quite a problem. If the æ are pared from their abnormal deep connections, y means of a tenotome freely used through the nosils, the cutaneous and subcutaneous tissues can be nfolded and drawn out so as to reconstruct the asal elevation. There may not be sufficient rigidity the tissues, however, to keep them in the desired osition; and if the bony bridge has been destroyed, e problem is more difficult. It has been proposed dissect up the nose by an incision from within the outh, under the upper lip, and to insert a metal ridge or support. This can doubtless be done with uccess. I have accomplished a good deal with plugs the nares, used until the new position was conrmed; have used spectacles of special construction o pinch up the soft tissues into a bridge; and have mployed plastic devices with much satisfaction.

The straightening of crooked noses can be accomlished only after very free separation of the cartilge and skin from the nasal and superior maxilliary ones. This is best done with a tenotome passed nto each nostril in turn. With it the mucous memrane is pierced and the tissues freely cut away from their bony attachments. The septum is then divided by knife or saw, and the nose forcibly bent into the traight position. A great deal of force should be pplied so as to twist the parts completely out of their bnormal relation. It is always well to over-correct he distortion because there will be a tendency of the ld condition to return. If the nose is bent to the ight, the surgeon should give it a marked twist to the eft of the middle line, and similarly to the right in eft deviations. After this has been done, steel pins, ne and one-half inches long, are thrust through the kin just below the nasal bones, and through the columella at the margin of the anterior nares, and used s levers to hold the nose in its corrected position. The pins should be retained about ten days or two weeks.

I have not considered the more elaborate procedures for reconstructing new noses from the arm, finger and forehead, nor gone into the present topic in great detail, because this paper is only suggestive. A consideration of all the operations of a cosmetic nature practicable upon the nose would make this communication much too long. I have, moreover, in another place, discussed many matters pertaining to this branch of surgery ("The Cure of Crooked and Otherwise Deformed Noses," Philadelphia, 1889). At this time I especially desire to call the attention of the medical profession to the fact that much can be done to aid sufferers from nasal disfigurements, and that those with bent, twisted, angular, tuberous or syphilitic noses should be given to understand that the condition is capable of great cosmetic improvement. The surgeon must use in this work his knowledge of plastic surgery, and adapt his operation to each individual case. Much more can be successfully done, in an operative way, to the nose than is usually believed.

THE SIGNIFICANCE OF AN HERNIAL SAC.

Read before the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, at Detroit, Mich., June 7, 1892.

[The name of the author does not accompany this paper.]

Hernia is full of interest; is fraught with imminent danger, and may come when least expected.

Modern progress has given a new impulse to early diagnosis. To recognize hernia in embryo is to anticipate all its perils. Hernia and sac seem indissoluble. Unhesitatingly the student of medicine associates the two. In whatever situation it occupies, a hernia is composed of a sac and contents. Practically this teaching is just a little misleading. For years past it has been my aim to impress my class with the importance of early diagnosis, that is, diagnosis before the formation of a sac, for with the sac come as probabilities all the calamities incident to the infirmity, viz.: inflammation, irreducibility, incarceration and strangulation; disasters embodying the significance of an hernial sac. The palliative cure of hernia is the permanent vacation of the sac; the radical cure, the extinction of the sac. Apathy on the part of the patient together with absence of intelligent solicitude on the part of the physician permits the formation of a sac. thus entailing all its incident hazards.

All mankind are, in the nature of their anatomy, predisposed to hernia, differing the one from the other simply in degree. The fibre of some men is short and tense; of others, long and lax. The abdominal wall is weak at certain points in all. The common habits and necessities of life impose oft repeated diminution of the capacity of the abdomen; but most of all feats of agility, such as jumping, lifting heavy weights, etc., test out the weak places, when points of least resistance necessarily bulge. Tenacity and elasticity of tissue in the standard organism may reinstate all, but there is a limit. The combined forces of the abdominal muscles concentrate against the feeble points of the parietes, the equilibrium is lost, a sense of weakness is felt, and the necessity for support is immediately experienced. All the organs alike, even those most distant. as well as those most fixed by mesenteric folds are forced towards the hernial sites. The cæcum has been found in an umbilical hernia, in an inguinal hernia on the left side. Anatomical knowledge alone would never have led us to entertain a suspicion of the possibility of these occurrences, but facts warrant the inference that there is no necessity for supposing elongation of the visceral ligaments a predisposing cause of hernia.

The ligaments of the liver, those of the spleen and the various membranous bands of the intestines in general, would be but feeble means of fixing such parts in their respective situations were it not for the fact that the abdomen is always completely full. The containing and contained parts react upon and reciprocally compress one another. It is by the effect of this moderate but equal and unremitting pressure that all the viscera mutually support each other. Doubtless the ligaments became stretched and permanently elongated as the result of repeated or continued descent of the intestines; but we are not cognizant of any facts to prove a congenital condition of the kind above alluded to. At first sight this circumstance regarding the elongation of the mesentery may seem to have very slight practical value, and that the cause of hernia is rather in a want of equilibrium between the pressure of the viscera and the resistance of the abdominal parietes, yet persons in whom an hernial sac exists, state that they are most troubled with the descent when out of health, when generally relaxed. If it be an anatomical truth that an elongated mesentery is a preliminary to hernia, the radical cure should begin by abridging it. Certainly the determining condition of hernia seems to be the relative preponderance of the predisposing and existing causes.

Practically the most important period in the progress of hernia is when weakness is felt and slight fullness is observed in the hernial site. At this period the parietal peritoneum pushed before the protruding viscus has a conical shape, therefore strangulation would seem to be impossible. Soon, however, the peritoneum so protruding reaches the connective tissue beyond the tendinous rings, there being less resistance it expands into a rounded shape when that portion corresponding to the resisting rings is relatively smaller. Now for the first time a sac appears, when strangulation is possible. For a time after the hernial sac acquires a neck, body and fundus, the neck is puckered within the grasp of the tendinous rings; if at this time the protruded peritoneum is returned, the puckering disappears, thereby effacing the orifice of the sac, cure being complete. If at this period strangulation occur, the nip is at and by the tendinous borders. At a later time the orifice of the sac itself takes on organization which sufficiently explains all the phenomena of which it is the focus.

The period prior to the organization of the sac is, as we have written, the most important in the history of hernia. For a time, even if the tumor be quite prominent, the neck of the sac is only folds of peritoneum which are readily obliterated on the reduction of the mass. Later the peritoneal plaits adhere, the orifice of the sac becoming an independent structure, or a permanent and distinct organ, annexed to the peritoneum. From this moment the orifice has an evolution peculiar to itself, becoming the seat of remarkable changes. The serous surfaces are not alone the seat of the action relating to the organization of the orifice, for subserous connective tissue changes of no less interest take place. The adipose tissue disappears although the person be fat. The connective tissue is transformed into an highly vitalized, vascular structure, changing later into a fibrous layer which interlacing in every direction comes to resemble the dartos. This dartos-like layer having contractile properties may play its part in obstruction and strangulation, certainly this dartos structure accounts for the constant tendency to contract which characterizes the orifice of the vacated sac, as well as the tendency to obliteration after herniated organs cease to act upon it. The contractile quality of the sac tissue which promises so much in the direction of cure provided the prolapsed organs are kept up is a constant menace when precautions are neglected. Incarceration, inflammation and strangulation are penalties annexed to inattention to the truss. From the moment a hernial sac is evolved begins the formidable array of disasters which constantly beset the victims of hernia. Again, the dangers increase apace till the offending organ is obliterated by its own contraction or removed by surgical aid. Early diagnosis of hernia, the prevention of sac, seems the only solution of the difficulty. The practicability of this most important point is the question. To engage the coöperation of the patient and to awaken the profession to the importance of early attention is the only hope.

The diagnosis of hernia is quite as easy at an early period as later; the symptoms the same, differing only in degree. The same subjective and objective signs, the sense of uneasiness, the feeling of weakness, the impulse on succussion of the abdomen, the comfort of recumbency and aggravation on assuming the erect posture, the surgeon readily demonstrating to himself the opening through which the protruding parts play.

Unfortunately we think of hernia as an established infirmity, sac and contents always in our minds. We would shift the interest in this subject to the period anterior to the formation of the sac, when the disease is new or just developing. We would have hernia recognized before it has grown old, an exaggerated form of disease. If early diagnosis is so important to the success of a surgical operation, how much more important when early diagnosis anticipates the necessity of an operation, nay more, prevents the disease, the surgeon by a simple mechanical contrivance restoring the patient. Unfortunately the surgeon does not see cases of hernia till the sac is perfected. The neglect of the patient and the want of intelligent concern on the part of the practitioner at a sufficiently early period fortunately or unfortunately furnish the data for the larger portion of surgical literature which is the boast of our profession.

Preventive medicine is the goal. A knowledge of causes and their apprehension must however be the aim to the end.

Agencies of injury and disease once established, the relative impotency of our art becomes a painful realization.

The Mississippi Valley Medical Association will hold its eighteenth annual session at Cincinnati, Wednesday, Thursday and Friday, October 12, 13 and 14, 1892, under the presidency of Charles A. L. Reed, M.D., Cincinnati. An excellent programme, containing the best names in the valley, and covering the entire field of medicine, will be presented. An address on Surgery will be delivered by Dr. Hunter McGuire, of Richmond, Va., President of the American Medical Association. An address on Medicine will be made by Dr. Hobart Amory Hare, Professor of Therapeutics and Clinical Medicine, Jefferson Medical College, Philadelphia. The social as well as the scientific part of the meeting will be of the highest order. The officers of the Pan-American Medical Congress will hold a conference at the same time and place.

The next meeting of the Kansas State Society will be held in Topeka, in May, 1893.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1274, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, AUGUST 20, 1892.

TWO MISTAKES.

A prominent professor in a recent address, asserted positively, that mistakes by the modern physician were always personal reflections on his training and judgment. This recalls two remarkable cases never published, that are wide exceptions to this strange assertion.

Over thirty years ago a warm controversy was carried on by the leading surgeons of this country, on the question of union from fracture of the neck of the femur. Intra-capsular fracture was considered never to heal by bony growth. All the cases which seemed to prove the contrary were considered partially within and without the capsule. Specimens to prove either side of the question were sent for examination to all leading surgeons, and opinions were given freely. Exhaustive papers were read and debated in the societies. The leading surgeons who believed in bony union within the capsule procured a very remarkable specimen, at the London University Hospital, which was submitted to all the leading London and Paris surgeons, and declared to furnish conclusive evidence of fracture and bony growth within the capsule.

This and other less marked specimens were examined by the surgeons of this country, and accepted as proving the fact, by the most critical opponents. The controversy seemed settled, when a country physician who was examining the specimen, recognized a disparity of weight compared with other similar bones. A closer study revealed a plaster of Paris head joined to the bone, so ingeniously as to escape the most critical examination. This specimen had been studied by over twenty of the leading surgeons of the world, and its external appearances had been accepted as unmistakable proof of bony growth of intra-capsular fractures of the neck of the femur.

Why these surgeons had not discovered this fraud was a mystery. Many of them were, and are yet the great fathers of medical science, whose names and works will live far down into the future.

The second instance is more modern. A nervous Irish girl had intercourse while coming to this country. A few months later she exhibited many signs of pregnancy, and was ruthlessly turned out on the street. A young doctor of wealth and leisure became convinced that it was not pregnancy, and accordingly had her examined by many leading specialists, each of whom differed with him. He then took her to some of the leading authorities of the great medical centers of the country. The diagnosis of all was pregnancy, with some obscure complications. Finally the girl died from peritonitis, and a post-mortem revealed nothing, with no indication of conception or change of the uterine walls. The only possible explanation was that most of the symptoms were mental, and in support of this it was ascertained that the girl had read in a handbook of medicine the various symptoms of pregnancy, and firmly believed she was in this condition. The peritonitis of which she died was of the same character. Thoroughly trained physicians in active practice fully recognize the possibility of mistake and error in the diagnosis, and are never dogmatic; and are also slow to condemn any one who has formed a wrong opinion.

Therapeutical differences of opinion are a part of the individuality of the man. Differences of diagnosis date from the perception and power of reasoning, together with experience, memory and training. Of necessity it will vary widely, especially if any obscurity or complications of symptoms are present. One of the most eminent London physicians had a clinical clerk who recorded all the facts of the case, which were read over at leisure and studied before an opinion or diagnosis would be given.

Physicians should exercise the same caution and care in forming opinions that judges display. Occasions rarely occur in which time cannot be taken to study and consider the meaning of the symptoms. It is no mark of greatness to be able to diagnose the case at once, or in the popular sense see through the case at a glance.

It is no sign of ignorance or incompetency to fail to understand the case. To teach students that positive diagnosis can be made in all cases is an error. The rapid increase of means and appliances for ascertaining facts of disease and diseased conditions require more study and training, and capacity for deductive reasoning. The older physician who makes a diagnosis often by mere intuition, may be quite as accurate as the younger man with a vast array of facts from instruments of precision. In one case we can follow and correct such reasoning, but in the other we cannot. CARLYLE said mistakes and errors are inseparable from every human being, irrespective of all conditions. No field of thought requires more accurate perception and critical reasoning than that of medicine. The judge realizes that his opinion and the facts on which it is based will be reviewed by others, and it is a matter of personal pride to be correct. In a higher sense the judgment of the physician should be sustained by the progress and history of the case. A court of last resort will finally pass on his judgment, beyond the selfish levels of pride and personality.

THE LOCALIZATION OF TUBERCULOSIS IN THE HERNIAL SAC.

One of the most interesting examples of the localization of tubercular infection has been brought to our attention through the very novel contribution of Loutham in the *Medical Chronicle* April 1892. In one case a consumptive had a large scrotal hernia which was found on operation to be irreducble from tubercular peritonitis in the sac. The sac and testicle were removed together with complete recovery. In the second case a six year old boy without evidence of tuberculosis elsewhere was operated on for hernia. The sac was found covered with milliary tubercules and it was extirpated high up with prompt recovery.

Bruns[1] has lately studied thirteen cases of tuberculosis in the hernial sac. Of these seven were recognized as primary, while the remainder were simply part of a general peritonial tuberculosis.

It must then be concluded that primary (so called) tuberculosis of the hernial sac is simply a secondary focus. The localization of this focus depends on a diminished resistence in the hernial sac, due to mechanical causes. The primary focus being probably in the pulmonary side of the circulation.

The treatment of these cases is to be determined by the experience found in general peritorneal tuberculosis. Tuberculosis of the sac is not a certain indication to the radical operation. It calls for the complete extirpation of the sac and iodoform medication. It is not a certain indication to operation in a general tuberculosis. The recoveries in the fifteen cases now reported are encouraging.

ELECTRICAL EXECUTION.

Another electrocutive experiment has been successfully carried out in New York State. The period of contacts was thirty-seven seconds; twelve, ten, eight and seven seconds for the four applications. There was no burning of the flesh and no great muscular contraction during the contact. There were no disfigurements found after death as a result of the contact of the electrodes. The electrical current used was equal to 1,560 volts at seven ampères. The date of this last, and least objectionable electrocution was August 2, and the place was Clinton prison. The disagreeable features of this form of judicial death have been reduced to a minimum, in the light of the earlier experiences, especially last year at the Sing Sing prison. All public clamor against the method may be said to have been effectively stilled, for th present at least. Now it remains to be seen if other States will adopt the measure, in next winter's legislatures.

EDITORIAL NOTES.

New York City and its Croton Water.—The *New York Medical Journal* remarks editorially on the deterioration of the croton water. In its unfiltered stata, its color and odor are not such as would inspire confidence. Albuminoid ammonia is reported by the official chemists to show a decided increase, while the presence of vegetable matter in excess is revealed by the microscope. If this condition persists a reported increase in cases of enteric fever must be expected among those who use unfiltered and unboiled water.

Headache Treated by Chloralamid.—The following formula, for the treatment of headache and insomnia from exhaustion, has been recommended by Gallani in *Medicine Moderne:*

Chloralamid, 30 grains.
Hydrochloric acid, dil., 5 drops.
Syrup, 2 drachms.
Distilled water, 2 ounces

Fifteen grains is the dose recommended, to be repeated, although thirty grains would probably be prescribed by some others who have had an experience with chloralamid as a hypnotic. Cold water should always be used in making this and similar solutions, since the drug is decomposed when hot water is used. By the addition of a little alcohol or spirituous liquor, in which the drug is readily soluble, the successful preparation of these solutions is ensured. The subcutaneous injection of a four per cent. solution of chloralamid has been found efficient against insomnia and abdominal pain, such as alleged "hepatic colic" and secondary neuralgia due to carcinoma of the rectum.

Life Insurance without Medical Examination.—It is stated that three London companies have so modified their rules that those applicants who desire to avoid medical examination, can do so by the payment of a specially arranged scale of premiums. The same step has been under consideration by several of our American companies, with the result of declining to go into the venture until the success of the British companies shall have been proven.

The *Chicago Medical Recorder*, edited by Dr. Archibald Church, and previously published by W. R. Keener of Chicago, is now being published by the M. H. Kaufmann Medical Publishing Company.

DOMESTIC CORRESPONDENCE.

To the Editor of the Journal of the American Medical Association:

Your editorial in The Journal of Aug. 6, entitled "The Surgeons at Homestead" is misleading and calculated to cast censure upon worthy men, engaged in the discharge of a most unpleasant duty.

The punishment inflicted upon Private Wm. L. Iams, Co. K. 16th Reg., for shouting "Three Cheers for the man who shot Frick" was not greater than the offense merited. All, good, law-abiding citizens who are conversant with the facts, and with the lawless spirit which pervaded the community at Homestead, at the time of the strike, and the danger of this same spirit extending to the soldiers, acknowledge the truth of the above statement. And the fact that Lieut. Col. Streator was last night unanimously, re-elected Lieutenant-Colonel of his regiment proves that this is also the opinion of his brother officers.

---

[1] Tuberculosis herniosa Beiträge zur Klinchirosgie Bd. IX.

Private Iams had proven himself, on former occasions, to be a bad soldier. At Moreland, two years ago, he was punished for insubordination. At Kensington, one year ago, he was again punished for breaking through the guard. At Homestead on Thursday (two days before his last treasonable conduct) he had slept on his post, and on Friday was punished by being compelled to carry a log on his shoulder. On the next day (Saturday) when our whole community was shocked by the murderous attack upon Mr. Frick, this same man stood up in his tent, and shouted "Three cheers for the man who shot Frick." This in the presence of our citizen soldiers. It is much to their credit that the remark was received with indignation. Iams was asked to recall the expression which he emphatically refused to do, and it was then that the order was given "that he be tied up by his thumbs, and that the surgeons stand by, and see that no harm befel him." In the army, or elsewhere, when punishment is administered to a culprit, it is customary, as it is humane, to have a physician present to see that the punishment is not carried farther than the criminal is able to bear. The tieing up of a soldier by the thumbs, is a mode of punishment which has been sanctioned in the army by long usage. In the case of Iams the surgeons were ordered to stand by and see that *no harm befel him*. This they did. They saw to it that he could stand in such a manner that he could take all the weight of his body, when he so desired, upon his feet. They counted his pulse, and watched his respiration, and when in their opinion he began to show symptoms of being physically injured, they ordered the punishment stopped. Surely there was no cruelty or brutality exhited by the surgeons.

In your Journal you say, "it is not the province of this Journal to discuss the action of the Colonel in ordering the punishment which he did. But the actions of the surgeons becomes a fit subject for discussion by the medical profession. It is generally admitted that medicine is the healing art, and that the great duty of the physician is to relieve pain, and not to inflict it, except it be for the purpose of saving life, or cutting short other suffering." Again, you say, "we care not what military law may be, *it was the duty of those surgeons to as medical men, to refuse to carry out the orders of the Colonel, to tender their resignations on the spot, if necessary, or even to suffer punishment for insubordination.*

These remarks would have some little pertinence, if the surgeons had been ordered to inflict the punishment, but they were not so ordered, they were only ordered "to stand by and see that no harm befel the culprit." Surely so far as the surgeons were concerned this was in the direct line of their duty. To have refused would have been to be untrue to their office, to the medical profession and to the culprit. All of the actions of the surgeons were on the side of humanity. Being personally acquainted with the surgeons at Homestead I can vouch for their ability as surgeons, and character as men. They knew their duties, and are incapable of doing any act of cruelty. There is a maudlin sentimentality in the community in regard to criminals and their punishment, which, unless checked, will destroy all law and order.

Iams deserved the punishment which he received and the surgeons at Homestead, should have been commended, instead of being censured for the manner in which they discharged a most disagreeable duty. J. B. Murdoch.

Pittsburgh, August 10, 1892.

In our reference to the surgeons who were present at the time of the punishment of private Iams, we fairly reflected the sentiments of the people as shown by many columns of comments in the current press. In no way do we justify Iams for his senseless and perhaps criminal act, but as war did not exist and the town of Homestead was not under martial law, and the regiment one of citizen soldiers, under orders to preserve the peace, the offense was not of the grade to demand such a sentence without a trial by court martial. The conditions were extremely exasperating, and should have been an occasion for the exercise of a cool judgment, rather than the autocratic power of an impulsive despot, which placed the surgeons in an unpleasant dilemma. A refusal to obey the command of a superior officer in the army is a most serious breach of military discipline.

Duty to obey an officers order, which involves such severe physical punishment as to require a surgeon to take a professional part in executing the sentence, is questionable. This is undoubtedly the case, where the culprit has had neither semblance or pretense of trial, in a time of peace, and is certainly an occasion to call for a protest not only from the surgeons immediately concerned, but from the profession at large.

After the associated press report of this unfortunate affair the *Medical Review* comments as follows:

> Such is the story which is told. Eminent legal authority claim that the punishment was not only uncalled for, but unjustifiable and illegal. We have nothing to do with this phase of the question. Whether legal or otherwise, the surgeons had no moral right to act in the position of *participes criminis* in a torture whose equal can only be found in the annals of the Inquisition. The medical officers degraded their profession to the extent of not only countenancing such an infamous act, but of watching the miserable victim to see how much torture he could bear. They felt his pulse and watched his heart until he was limp and apparently unconscious. They did not have the manhood, much less humanity, to protest with the brutal Colonel against such unheard of punishment. These are the men to whom delicate women and puny children are to be confided! These are the kind, ministering angels who are to smooth the pillows of the afflicted and assuage the pains of the diseased.
>
> We have more respect for the American Indian after this. The Chinese torture as a custom can no longer be revolting. These people have been educated to their peculiar methods, and only employ them on their enemies or on criminals of the deepest dye: The medical officers of the Tenth Regiment Pennsylvania National Guards watch a fellow man and citizen suffering the tortures of the damned to please a Colonel who should be relegated to a position where he could be watched by a Humane Society.
>
> In whatever light this outrage is looked upon, there is no excuse for it. But the greatest dishonor, the greatest obloquy and shame is surely deserved by the self-styled physicians who could so degrade, so besmirch their profession as to drag it in the mire as they have done in the case of Private Iams. The incident will remain a lasting monument to the disgrace of medicine, more especially of American medicine, and it will take much to wipe out the stain which has thus been placed upon a large, honorable and humane body of men.

The editor of the *Lancet-Clinic* says:

> The present trouble at Homestead has been prolific in producing unpleasant and painful spectacles; but it seems to us that there has been nothing so barbarous as the punishment inflicted upon the soldier who dared to suggest the propriety of giving three cheers for the assassin of Mr. Frick. From a perusal of the account one would almost be led to the belief that the days of torture and thumb screws had not passed away.
>
> While we cannot sympathize with the sentiment of the man who desired to applaud attempted murder, much less do we sympathize with the brutality of tying a man up by the thumbs until he faints. Such barbarity should have no place in a civilized community, and the Colonel who ordered such punishment has disgraced his manhood and shown himself a bully and a tyrant. Further than this, we do not

believe that legal justification for this act could be obtained from any right-minded judge.

The medical men figured in a very unenviable light in this affair, and the part they assumed is a degrading one for any member of our humane profession to undertake. We are sorry they allowed themselves to act as torturers to his majesty, the Colonel of the regiment, and believe that a second sober thought will convince them that they allowed themselves to be made parties to a despicable and cruel punishment. Doctors, we cry shame upon you!

SELECTIONS.

Venereal Disease in Paris and Brussels.—Among 2,941 registered prostitutes in Paris, arrested for various reasons in 1891, 251 were found to be suffering from veneral disease. Of 2,637 clandestine prostitutes arrested under similar circumstances, 1,153 were infected. The proportion of disease was therefore about 8½ per cent. among the registered women, as against 43 per cent. among the clandestine prostitutes. In Brussels, where the regulations are very strict, the proportion of disease is somewhat less among the registered women, but among the clandestine prostitutes it has recently increased to such an extent that an additional ward has had to be opened in the St. Pierre Hospital for their reception.

Female Physicians and the British Medical Association.—According to the *British Medical Journal* for July 30th, a resolution was passed at the recent meeting of the British Medical Association at Nottingham, expunging a section of the articles of association that provided that no female should be eligible for election as a member of that association. The question was first agitated in 1878, when it was decided, by a large majority, to make no change. This recent action reflects credit on the association.

The Treatment of Chronic Suppurative Otitis. By Dr. H. Gradle, Chicago.—His observations are based on about 600 cases, and from a careful study of the results of treatment he formulates the following conclusions: "As long as the pus of otorrhœa smells fœtid, the treatment employed has exerted no curative influence on the disease," and conversely "the first sign of curative influence of any treatment upon the course of an otorrhœa is upon the odor of the discharge." To test for the odor, the meatus is mopped out with cotton on a probe, and the surgeon smells what is removed. He then recommends thorough syringing and the application of some form of antiseptic, such as boric powder, and on the following day to again test for the smell; and if the odor persists, the continuance of the same form of treatment will prove of no benefit. Unless the stagnant pus be thoroughly removed, the use of boracic acid or any other disinfectant cannot make the discharge odorless. The necessity of thorough cleansing of the meatus, tympanum, Eustachian tubes, etc., is insisted upon as being the first essential, and next the application of an antiseptic in such a condition that it can freely enter the various crevices. —*Archives of Otology*, 1892.

Antrectomy as a Treatment for Chronic Purulent Otitis Media. By W. Arbuthnot Lane, M.B., London.—Here Mr. Lane emphasizes the fact that the antrum has no anatomical or physiological relationship with the mastoid process or its cells, but that it is situated in the petrous bone, and is, physiologically and anatomically, a part of the middle ear, and that it plays a very important part in the pathology and causation of chronic purulent otitis media. He opens the antrum by the use of mallet and gouges, then scrapes the cavity with sharp spoons. Subsequently he removes overhanging bone, so that the gouged inner wall of the antrum is the apex of a cone. The paper is carefully written and well worthy of perusal.—*Archives of Otology*, 1892.

NECROLOGY.

Dr. Thomas Godrich, of Gravesend, New York, died July 27, 1892, of diabetes. He was a native of London, a doubly qualified practitioner of that city for many years, and an occasional attendant upon the Prince of Wales' family at Sandringham. He as was also the possessor of appointments in the Royal Volunteers, in the Humane Society, in the Fulham Health Office, in asonic relief, public vaccination and the Abbey Wood Infirmary, in the south-western part of London. He came to this country in 1885, and was in his fifty-fifth year at the time of his death.

Dr. Phillip Markbreiter, of Vienna, died July 20. In 1860, he founded the *Midizinal Halle,* which more recently received the title of *Wiener Medizinische Presse.* He was co-editor with Schnilzler of the *Medizinisch Chirurgische Rundschau.* About 1870, he withdrew from these and some other journals that knew more or less of his editorial work during many years.

Dr. Antoine Ruppaner, a former member of the Association, resident at Boston and New York, died August 2 at Pittsburgh. He was a native of Switzerland, having been born there about the year 1825. Professor Agassiz, of Cambridge, was interested in young Rüppaner and through his instrumentality took the Harvard medical degree in 1858. He began practice in Boston, adopting laryngology as his specialty, being among the pioneer specialists of Boston. About 1866 he removed to New York, locating for office practice at the fifth Avenue Hotel. Latterly he removed to the Hoffman House. His offices were replete with objects of art, finely bound books and choice curios. He was a bachelor and without heir of near kin, although leaving an estate valued at over half a million. His contributions to the journals were among the first of their kind in this country; and in 1868 he published a small handbook on laryngology and rhinoscopy on diseases of the throat and nasal passages. This latter was probably the first brochure, indigenous in this country, at a time when even the term rhinoscopy had a strange and uncertain sound to American ears.

MISCELLANY.

Medical Society of the Missouri Valley.—The annual meeting of this Society will be held at Council Bluffs, Iowa, September 15, commencing at 9 a.m. and continuing in session one day. Titles of papers should be sent prior to September 1, so they can appear on printed program mailed members at that date. F. S. Thomas, M.D, Sec'y.

Dr. W. Thornton Parker has accepted the invitation of the Faculty of the College of Physicians and Surgeons, Chicago, to deliver the course of lectures on Medical Jurisprudence during the approaching Session, 1892-3.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 6, 1892, to August 12, 1892.

Col. Charles T. Alexander, Asst. Surgeon-General U. S. A., is granted leave of absence for twenty-one days, to take effect upon the completion of the bond of Capt. Harry O. Perley, Asst. Surgeon U. S. A.

Col. Charles Page, Asst. Surgeon-General U. S. A., leave of absence granted is extended one month.

Capt. William C. Gorgas, Asst. Surgeon U. S. A., extension of the leave of absence granted is further extended twenty days.

Major Charles Smart, Asst. Surgeon U. S. A., is granted leave of absence for four months.

The Journal of the

American Medical Association

VOL. XIX. CHICAGO, AUGUST 27, 1892. No. 9.

ORIGINAL ARTICLES.

THE POWERFUL EFFECT OF SULFONAL IN ARRESTING THE CRAMPS OF FRACTURED LIMBS, AND REFLEX SPASMS FROM OTHER CAUSES.

Read before the Section of Surgery and Anatomy, at the Forty-third Annual Meeting of the American Medical Association, at Detroit, Mich., June, 1892.

BY EDWARD ANDREWS, M.D.,
OF CHICAGO.

Sulfonal was discovered only six years ago by E. Baumann. Chemical nomenclature has evolved for it the frightful name of diethyl sulphon-dimethyl-methan. Prof. A. Kast first reported on its qualities in *Die Berliner Klin. Wochenschrift*, in 1888, or four years ago. About three years ago my attention was turned to its remarkable power of arresting the spasms of fractured limbs by having given a dose for its supposed hypnotic effect, and finding instead a strong antispasmodic result. I published my observation not long afterwards in a short article. Since then I have continued my experiments, and now offer a condensed statement of the results.

It is curious that the numerous writers who have reported upon this new drug have almost uniformly confined their attention to its sleep producing influence, and overlooked its remarkable antispasmodic power. In fact Dr. W. F. Shick, writing in 1889 to the *Journal of Nervous Diserses* went so far as to say that the drug has no influence on motor nerves, nor on the muscles. Four or five writers, however, have caught slight glimpses of its antispasmodic power.

Forster, who is said to have administered not less than eighteen pounds of it, remarked that it is chiefly a motor depressor.

Roubinovitch in one case cut off a paroxysm of spasmodic asthma, by doses of fifteen grains.

A. S. Faulkner, of India, reported one case of chordee arrested by it.

J. M. Coates reported the greatest benefit in epilepsy, and in obstinate hiccough.

J. A. Jeffries reported five cases of chorea rapidly cured by the article.

My first observation was upon a case of painful cramps from a recently fractured femur. Morphine relieved the patient as long as he could keep awake, but as soon as he became drowsy the cramps returned. On changing to suflonal in fifteen grain doses the spasms were completely, arrested both in the waking and the sleeping condition. Repetition of the treatment in other cases of fracture showed always the same result.

A gentleman in a railroad accident received a slight fracture of the spine without any compression of the cord. He was harassed whenever he fell asleep by cramps of the inter-costal muscles adjacent to the injured vertebra. Sulfonal in fifteen grain doses arrested the trouble completely.

I may remark here that the drug is slow in its action, and where the cramps are only nocturnal, it is necessary to give either a large dose two or three hours before the sleeping time, or else to keep up the effect by using moderate doses three times a day.

I found one physician using this medicine to arrest the spasms of ejaculatory muscles which cause nocturnal emissions of semen. He gave six grains three times a day, and claimed excellent results. At his suggestion I tried it with good success, increasing the dose however, to eight grains.

From analogy I think the remedy will act well in cases of premature ejaculation in copulation, but I have not yet tried it for that purpose.

I have used sulfonal to arrest two cases of obstinate hiccough.

A gentleman was troubled for many years with nocturnal cramps of the legs and thighs, increasing slowly as his years advanced. Fifteen grains of sulfonal taken before retiring always prevented the spasms. After two months he found that a single dose would prevent the trouble for nearly a week. In about ten weeks more the course of the trouble seemed to be cured, so that he has now been a long time without requiring or taking any of the remedy.

A vigorous young man engaged in superintending the construction of a building, fell 32 feet, striking obliquely on a slope of timber, causing a severe contusion of the right sciatic nerve, without fracturing any bone. The thigh and leg of the injured side kept up a constant and painful jerking motion, resembling somewhat the movements in chorea. Two doses of sulfonal of fifteen grains each completely arrested the distressing movements.

It seems that the antispasmodic power of sulfonal is of more value than its sleep producing influence, and that it will prove of immense value in many cases in which no one has yet thought of giving it a trial.

No. 6 Sixteenth St., Chicago.

Dr. Brooks, of Iowa, stated that he had sustained a fall, resulting in a severe synovitis, which caused sudden spasmodic contraction of the leg during sleep. Sulfonal was prescribed and the spasms relieved from the first.

Dr. Murphy reported the case of a pregnant woman who suffered much at night from cramping in the legs. He prescribed sulfonal and found that one dose was usually sufficient to give relief. He has used the drug in two other cases with excellent results.

Dr. James A. Work, of Indiana, has a patient to whom he has been giving sulfonal for rheumatism, attended with cramps of the legs at night. The remedy acted admirably, but he had often been asked if there was not danger of a habit being formed. It was a relief to know that as the case progresses less of the drug is administered.

Dr. J. I. Strippmatre, of Philadelphia, stated that he had found the drug useful in the low nervous form of typhoid fever, accompanied with jactitations. He related a case in which there had been no sleep for six days. Twenty grains of sulfonal were given and the patient slept for twenty-four hours, only being aroused to take food. Recovery was thenceforth uninterrupted.

SECTION OF OPHTHALMOLOGY.

RECORD OF THE MINUTES.

The sessions of this Section were held in the morning and afternoon of June 7, 8, 9, and 10, 1892, in the club room of the Hotel Cadillac, Detroit, Mich.

TUESDAY JUNE 7.—AFTERNOON SESSION.

Dr. J. L. Thompson in the chair. Meeting called to order at 3:30 P.M. The Chairman opened the meeting with an address entitled "How Shall We Make the Meetings of Our Section More Attractive and Helpful?"

After the reading of the paper the reports of committees was the next order of business. No report having been received, the reading and discussion of the papers followed.

The first paper, entitled "Gradation of Lenses," was read by Dr. Dudley S. Reynolds, of Louisville, Ky. Dr. Leartus Connor moved that all gentlemen interested in the subject of ophthalmology then present in the room be invited to participate in the discussion of the papers. Carried.

The second paper, entitled "Some Peculiar Cases of Astigmatism," was by Dr. W. Cheatham, of Louisville, Ky. The author of this paper was absent.

The third paper, entitled "What May be Considered Normal Corneal Astigmatism, With Results from Keratometric Examination of One Hundred Emmetropic and One Hundred Ametropic Pairs of Eyes," was read by Dr H. V. Wurdemann, of Milwaukee Wis. The paper was discussed by Drs. H. D. Noyes, S. D. Risley, G. C. Savage, Eugene Smith and A. A. Hubbell, and the discussion closed by the author.

The fourth paper, entitled "A Study of the Eyes of Three Hundred and Fifty-seven Boys in the Penn Charter School, of Philadelphia, with Notes on the Examination of School Children," was read by Dr. B. Alex. Randall. It was discussed by Drs. Risley and Dowling and the discussion closed by the author.

The fifth paper, entitled "Latent Hyperopia," was read by Dr. Edward Jackson, of Philadelphia, Pa. It was discussed by Drs. C. H. Thomas, H. V. Würdemann, J. A. Lydston, F. C. Hotz and B. Alex. Randall, and the discussion closed by the author of the paper.

The sixth paper, entitled "The Fourth Degree Prism in the Correction of Hyperphoria," was read by Dr. A. E. Prince, of Springfield, Ill., and was discussed by Drs. Gradle and Risley, the discussion being closed by the author.

The seventh paper, entitled "On the Relation of the Motor Muscles of the Eyes to Certain Facial Expressions," was read by Dr. George T. Stevens, of New York. Three other papers appeared on the list, the authors of which were absent.

The Chairman then announced the Nominating Committee, as follows: Dr. F. C. Hotz, Dr. J. J. Chisolm, and Dr. Leartus Connor.

Dr. S. C. Ayres made a statement from the Executive Committee concerning the registration fee of one dollar, and to what this amount of payment would entitle each member, stating that he would introduce a resolution covering the ground. Dr. Ayres's remarks were discussed by Dr. Eugene Smith. On motion the meeting adjourned.

WEDNESDAY, JUNE 8.—MORNING SESSION.

Dr. J. L. Thompson in the chair. Meeting called to order at 9 A.M. The minutes of the previous meeting were read and adopted.

The first paper, entitled "Immature Cataract and the Best Method for Hastening Maturity," was read by Dr. J. A. White of Richmond, Va. The paper was discussed by Drs. Chisolm, Minney, Hotz, Tilley, Baker, Prince and Frothingham, and the discussion closed by the author.

It was then moved and carried that the discussion of the papers concerning cataract be postponed until all of them had been read.

The second paper, entitled "Treatment of Incipient Cataract," was read by Dr. A. J. Erwin, of Mansfield, Ohio.

The third paper, entitled "Method and Results of Simple Extraction," was read by Dr. H. Knapp, of New York. These papers were discussed by Drs. Chisolm, Fox, Frothingham, Noyes, Smith, Scott, Minney, Randall and Risley, and the discussion was closed by Drs. Erwin and Knapp. On motion the meeting adjourned.

WEDNESDAY, JUNE 8.—AFTERNOON SESSION.

Dr. J. L. Thompson in the chair. Meeting called to order at 3 P.M.

The first paper, entitled "New Operation for Trichiasis and Distichiasis—Galvano-Cautery," was read by Dr. Eugene Smith, of Detroit, Mich. The author of the paper also exhibited a patient on whom this operation had been performed. The paper was discussed by Drs. Hotz and Savage, and the discussion closed by the author.

According to the by-laws, the Committee on Nominations, consisting of Drs. F. C. Hotz, J. J. Chisolm and Leartus Connor, reported the following officers for the ensuing year: Dr. S. D. Risley, of Philadelphia, Chairman. Dr. Henry Gradle, of Chicago, Ill., Secretary. On motion the Secretary was directed to cast the ballot of the Society for these nominations. He accordingly carried out the instruction of the Society in this request. Drs. Risley and Gradle then accepted the offices to which they had been nominated in brief speeches.

Dr. S. C. Ayres on behalf of the Executive Committee then presented the following resolution which was adopted:

"The Executive Committee recommend that a registration fee of one dollar be assessed each year on every active member. In consideration of this fee, the member will receive one bound copy of the Transactions for the current year."

The second paper entitled "The Pathology and Treatment of Infantile Cataract," was read by Dr. A. R. Baker, of Cleveland, Ohio. The paper was discussed by Dr. Randall, and the discussion closed by the author.

The third paper, entitled "A Case of Congenital Ectopia Lentis," was read by Dr. George Friebis, of Philadelphia. The paper was discussed by Drs. Bryant, Randall, Morrow and Smith, and the discussion closed by the author.

The fourth paper, entitled "Injuries to the Lens with Cases," was read by Dr. B. L. Millikin, of Cleveland, Ohio. The paper was discussed by Drs. Ayres, Jackson, Aschman, Smith and Lippincott, and the discussion closed by the author.

The Secretary then announced that Dr. Charles A. Oliver, of Philadelphia, was unavoidably detained, but had sent an abstract of his paper. On motion the Secretary was directed to read the abstract, the title of the paper being "Clinical History of a Case of Successful Extraction of a Piece of Steel from an Iris and Lens by an Iridectomy, With Subsequent Absorption of the Lens Substance and Recovery of Normal Vision." It was moved that the paper be transmitted to the Executive Committee with power to act on its admission to the Transactions. The Secretary then announced that Dr. T. E. Murrell, of Little Rock, Ark., was unavoidably absent, but had sent his paper and an abstract of it. It was moved and adopted that the abstract be read. The Secretary then read an abstract of a paper, entitled "Eye Injuries Considered in Relation to Sympathetic Affections," by Dr. T. E. Murrell, of Little Rock, Ark. It was moved and adopted that the paper be referred to the Executive Committee with power to act. These motions were made after Dr. Hotz had pointed out the necessity of not admitting to the Transactions any paper unless the author were present himself, or had at least sent with his paper a full abstract of the same which should be read to the Society. Similar remarks were made by Drs. Ayres and Smith.

The fifth paper, entitled "The Advantages of Optico-Ciliary Neurotomy Over Enucleation," was read by Dr. J. J. Chisolm, of Baltimore, Md. It was discussed by Drs. Smith, Risley, Hotz and Ayres, and the discussion closed by the author.

The sixth paper, entitled "Surgical Treatment of Trachoma," was read by Dr. J. E. Weeks, of New York. The paper was discussed by Drs. Würdemann, Hotz and Knapp, and the discussion closed by the author. On motion the meeting adjourned.

THURSDAY, JUNE 9.—MORNING SESSION.

Dr. J. L. Thompson in the chair. Meeting called to order at 9 A.M. The minutes of the previous meeting were read and approved.

The first paper, entitled "Thiersch's Skin Grafts in Ophthalmic Surgery," was read by Dr. F. C. Hotz, of Chicago, Ill. Dr. Hotz first stated that he desired to change the title of his paper to "Thiersch's Skin Grafts in the Treatment of Pterygium." The paper was discussed by Drs. Prince, Savage, Starkey, Baker, Minney and Noyes, and the discussion closed by the author. Dr. S. C. Ayres moved that papers sent in by title, but not represented by their authors or by abstracts, should be excluded from the Transactions. Carried.

The Secretary announced that Dr. C. J. Lundy, whose name appeared in the list of the first afternoon session, had died; that his paper was, however, prepared and at the disposal of the Society, the paper being in the possession of the deceased member's family. Dr. G. C. Savage moved that a committee be appointed by the Chair who should draw up a resolution expressive of the Society's sorrow at the death of its fellow member. The Chair appointed on this committee Drs. G. C. Savage and Leartus Connor. The Committee has forwarded the following minute:

WHEREAS, The Ophthalmological Section of the American Medical Association, at its meeting in Detroit, June, 1892, learns of the death of one of its members, Dr. J. C. Lundy, therefore be it

Resolved, That as a Section we mourn the loss of an indefatigable worker in ophthalmology, and of an esteemed contributor to the prosperity of the Section.

Resolved, That we deplore his loss to his family, the medical profession, and his large circle of friends.

Resolved, That we tender to the family of our deceased brother our heartfelt sympathy.

Resolved, That a copy of these resolutions be sent to the family of the deceased.

G. C. SAVAGE, Nashville, Tenn.
LEARTUS CONNOR, Detroit, Mich.
Committee.

The second paper, entitled "Osteoma of the Orbit; Removal With Preservation of the Visual Functions," was read by Dr. Edward Jackson, of Philadelphia. The third paper, entitled "Orbital and Ocular Growths with the Report of Three Cases," was announced as conjointly the work of Drs. J. A. White, of Richmond, Va., and William M. Gray, of Washington, D. C., and was read by Dr. J. A. White. The fourth paper, entitled "A Case of Rare Form or Orbital Tumor," was read by Dr. George E. Frothingham, of Detroit, Mich. It was moved and carried that all of the papers referring to orbital disease should be discussed together. The papers were discussed by Drs. Knapp, Reeves, Chisolm, Ayers and Johnson. The discussion was closed by Drs. Frothingham and White.

The Secretary announced that Dr. J. G. Carpenter, of Stanford, Ky., who was listed for a paper entitled "Tumor of the Cornea," was absent, but had sent his paper and an abstract of it. It was moved and carried that Dr. Carpenter's paper be referred to the Executive Committee with power to act.

The fifth paper, entitled "Treatment of Keratoconus by Means of the Galvano-Cautery and Iridectomy," was read by Dr. Robert D. Gibson, of Youngstown, Ohio. The paper was discussed by Drs. Noyes, Knapp, Jackson, Chisolm and Savage, and the discussion was closed by its author. On motion the meeting adjourned.

THURSDAY, JUNE 9.—AFTERNOON SESSION.

Dr. J. L. Thompson in the Chair. Meeting called to order at 2:30 P.M.

The first paper, entitled "The Etiological Relation of Nasal Anomalies to Diseases of the Eye," was read by Dr. H. Gradle, of Chicago, Ill. It was moved and carried that all papers relating to nasal and lachrymal disease be discussed at the same time. The second paper, entitled "An Operation for Stricture of the Lachrymal Duct," was read by Dr. Charles Hermon Thomas, Philadelphia.

At this point Dr. J. L. Thompson, the Chairman, announced that owing to a notification of serious illness in the family, he would be obliged to ask to be excused from further attendance. Dr. G. C. Savage moved that a vote of consolation be extended to Dr. J. L. Thompson, and also a vote of thanks for his efficient services as Chairman of the Section. This resolution was unanimously adopted. On motion, Dr. S. D. Risley, of Philadelphia, was requested to take the chair.

The third paper, entitled "Heterophoria as a Cause of Rhinitis and Tinnitus Aurium," was read by Dr. Leartus Connor, of Detroit, Mich. On motion the meeting adjourned, to meet at 9 o'clock on the following morning.

FRIDAY, JUNE 10.—MORNING SESSION.

Dr. S. D. Risley in the chair. Meeting called to order at 9 A.M.

Dr. C. H. Thomas rose to inquire whether it was in order for a member of the American Medical Association to be registered in two Sections at one time. In reply Dr. Johnson stated such procedure was perfectly proper.

The minutes of the previous meeting, after two corrections were, adopted.

The first paper, entitled "Conservatism in the Treatment of Diseases of the Lachrymal Passages," was read by Dr. S. D. Risley, of Philadelphia, Dr. Edward Jackson occupying the chair in the mean time.

The second paper, entitled "Treatment of Epiphora," was withdrawn by its author, Dr. H. M. Starkey, of Chicago, Ill., who asked to be excused from presenting it owing to his inability to fully prepare his manuscript on account of ill health. It was moved that his excuse be accepted. Carried.

The third paper, entitled "Closure of the Lachrymal Puncta in Dacryocystitis as a Barrier Against Infection of the Wounded Eyeball," was read by Dr. G. A. Aschman, of Wheeling, West Va.

It was moved that Dr. Gould's paper, inasmuch as it pertained to the subject under discussion, be read in connection with the papers on lachrymal disease; hence the fourth paper, entitled "A Method of Infection, Treatment and Prophylaxis of Purulent Conjunctivitis," was read by Dr. G. M. Gould, of Philadelphia.

This series of papers was discussed by Drs. Gradle, Starkey, Gould, Tilley, de Schweinitz and Connor, and the discussion was closed by Drs. Thomas, Risley, Aschman and Gould.

It was announced that Drs. Thomas H. Fenton and H. Earnest Goodman, of Philadelphia, were unavoidably absent and could not present the papers for which they were listed.

The fifth paper, entitled "Insufficiences of the Oblique Muscles and How to Treat Them," was read by Dr. G. C. Savage, of Nashville, Tenn., he having substituted this paper in place of the one for which he was listed by consent. The paper was discussed by Drs. Gradle, Thomas and Connor and the discussion closed by the author.

The sixth paper, entitled "Monocular Diplopia," was read by Dr. R. Tilley, of Chicago, Ill.

The Secretary announced that Dr. Oliver Moore, of New York, was absent, but had sent his paper and an abstract of it. It was moved that the paper be referred to the Executive Committee with power to act.

On motion of Dr. Jackson it was resolved to complete the work of the Section during the morning session, and to dispense with the afternoon work. Accordingly the first paper was called, and the Secretary announced that its author, Dr. Fulton, was absent.

The seventh paper, entitled "Embolism of the Central Artery and Thrombosis, with the Report of an interesting Case," was read by Dr. S. C. Ayres, of Cincinnati, Ohio. The eighth paper, entitled "Embolism of the Central Artery of the Retina, with the Report of Three Cases," was read by Dr. G. E. deSchweinitz, of Philadelphia. These papers were discussed by Drs. Jackson and Ayres.

The ninth paper, entitled "Report of a Case of Zonular Atrophy of the Choroid," was read by Dr. Tilley, of Chicago, Ill.

The Secretary announced that the authors of the remaining papers on the list were absent, and that no abstracts had been sent.

It was then announced that Dr. J. L. Thompson had sent a letter containing his thanks for the expressions of sympathy which he had received from the Section.

It was moved that a vote of thanks be extended to the retiring Chairman and Secretary. This motion was unanimously adopted. On motion the meeting was adjourned.

The Executive Committee of the Section of Ophthalmology for the ensuing year, according to the resolution adopted at the meeting in Washington, will consist of Dr. S. C. Ayres, 64 West 7th St., Cincinnati, Ohio, Dr. F. C. Hotz, 36 Washington St., Chicago, and Dr. J. L. Thompson, 20 West Ohio St., Indianapolis. Ind., Dr. Thompson taking the place of Dr. Edward Jackson, whose term expires.

DR. J. L. THOMPSON, *Chairman.*
DR. G. E. DE SCHWEINITZ, *Secretary.*

HOW SHALL WE MAKE THE MEETINGS OF OUR SECTION MORE ATTRACTIVE AND HELPFUL?

Read in the Section of Ophthalmology, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY J. L. THOMPSON, M.D.,
PRESIDENT OF THE SECTION, OF INDIANAPOLIS, IND.

In view of the many subjects of interest contained in our present programme, it would seem that a departure from our former custom is needed.

I shall therefore, instead of reading an address on the "Progress of Ophthalmology" (a subject with which you are all familar) simply mention to you what I believe to be the most attractive feature of our sessions, namely: the discussion which follows the reading of papers. Dispense with this, or devote too short a time to it and our meetings are unprofitable. Cultivate and foster it, then the converse obtains.

Of course,it is highly essential, that we have a sufficient number of ably written papers for our consideration, but if too many are read, the object of our meeting together is defeated and we go hence almost as barren of results as if we had remained away. It is on this rock that the chairman and secretary are liable to founder; because in their efforts to provide material, they usually have to invite many to contribute; could they know before hand just who would respond favorably, but few mistakes could happen, but dealing with unknown numbers they are just as likely to have too many as too few, when disaster follows.

Would it not be wise to give the matter over to the executive committee, whose duty it should be to decide as to the papers which should be read before the Section, and those by title only?

Subjects are often presented which have cost their authors months of painstaking research and yet, though they be the most ably prepared, if no discussion follows, they might as well have been placed in some medical journal and sent to us for perusal in our homes, at our leisure. But if on the contrary a full and free discussion follows, we go away amply repaid for any sacrifice we have made; we are refreshed and greatly benefited by this comparing of ideas and experiences, lifted as it were out of the ruts of routine work to the higher plane of progressive Ophthalmology.

So in the place of an address by your chairman we will immediately proceed to the work which is before the Section.

GRADATION OF LENSES.

Read in the Section of Ophthalmology at the Forty-third Annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY DUDLEY S. REYNOLDS, A.M., M.D.,
PROFESSOR OF OPHTHALMOLOGY, OTOLOGY AND MEDICAL JURISPRUDENCE IN THE HOSPITAL COLLEGE OF MEDICINE, MEDICAL DEPARTMENT OF THE CENTRAL UNIVERSITY OF KENTUCKY; SURGEON TO THE EYE AND EAR DEPARTMENT OF THE LOUISVILLE CITY HOSPITAL.

The gradation of lenses has been a perpetual source of discontent amongst all those who seek scientific accuracy, and the want of a uniform system is universally recognized. I had the honor, at the Ninth International Medical Congress, to read a brief paper on the necessity for reform in the manner of designating lenses, and in conclusion, I suggested the propriety of designating them according to the angle of refraction, as for example: begin with a lens the refracting powers of which equal an angle of 15′; the next in the series 30′; 1°; 1° 30′; 2°; 2° 30′ etc., up to the maximum angle of deviation of the pencil of refracted light. At the Cincinnati meeting of the American Medical Association, in May 1888, I presented the subject in a brief review of the principles, upon which lenses are constructed, and presented a table embracing a series of forty-two lenses, graded in minutes and degrees, according to the angle of refraction as determined by the angle of deviation the lens produced in a point of light transmitted through a frosted disk. The value of a lens must of course depend upon its angle of refraction, whether it be a prism, cylinder,sphere or a combination. If we adopt the method of gradation by the angle of refraction, we shall have no more such confusion, as the student must encounter in his attempts to *determine the relative* value of the metrical, the so-called inch system, or those *denominated in fractions of the radius* of the quadrant.

Professor *Loring says, in discussing the subject*: "The metre is taken as the unit, and each metre is *called a dioptric. As the French metre is equal to* thirty-seven inches, 1 D. = $\frac{1}{37}$ expressed in the old style." Dr. Claibourne of New York, suggests that, "the dioptre is equivalent to $\frac{1}{36}$ or $\frac{1}{40}$ according as the French or English inch is *taken* as *the* standard." Professor Landolt says: "One dioptre is to be *taken* as 37 *Paris* inches, or 39-5 English inches."

In England, distances are measured,as in the United States, by lines,inches,feet and yards, linear measure. In France, and some other countries, which have adopted the French system of millimeters, centimeters and meters, the metrical system of grading lenses harmonizes with this method of linear measurement, but it does not harmonize with either the English or American methods of linear measurement. To show how far this confusion extends, I invite your attention to the following, from Professor Noyes recent text book on diseases of the eye (p. 91): "I have noted with the same optical error uncorrected, say 1 D. or 2 D., differences of vision varying between $\frac{20}{40}$ and $\frac{20}{100}$". All through the literature of this subject, are found just such confusing statements. Now, the state of vision, according to Professor Snellen's method,is determined by ascertaining the capacity of the eye to perceive objects under a definite angle, illuminated by parallel light. Assuming that the range of accommodation does not extend quite so far as twenty feet, this is taken as the proper distance, beyond the range of accommodation, where objects may be placed for the determination of the refraction of the eye, and the relative acuity of vision with parallel light. Twenty, therefore, meaning English feet, is the numerator, and the size of the test object for determining the angle of vision, the denominator of the fraction used to express the state of vision, uninfluenced by the accommodation.

The fractional system of dividing the quadrant of the crown glass sphere has become part of the classical literature of mathematical science. It was used for designating lenses for spectacles, beginning with Friar Bacon, about 1282, descending in unbroken lines, until 1867, when the International Ophthalmological Congress, held at Paris, appointed a committee to investigate and report in favor of a uniform system of designating lenses. The Committee reported in favor of the metrical scale of focal lengths, having an interval equal to a lense of two hundred and forty centimeters focus. Since that time, Pœtz and Flohr of Berlin, with their lenses graded in Prussian inches of focal lengths, and Nachet and Son, with their series, graded in Paris inches, have no longer just grounds of dispute with English opticians, for they too, have adopted the metrical scale of grading lenses, still measuring distances by the old English standard, and recording results by the hap-hazard methods of unreasoning custom.

Dr. Edward Jackson of Philadelphia, deserves the thanks of the scientific world for his successful work in advocacy of the adoption of the angle of deviation of refracted light as a test of the value of prisms. Following this line precisely in the footsteps of Dr. Jackson, we shall be forced to adopt the angle of refraction as the test of value of all lenses, and we should designate them accordingly, in minutes, and degrees, thus harmonizing the practical application of the science of optics with those principles employed in the determination of the optical properties of the human eye, with the same mathematical principles elucidated by the great Astronomers and *Mathematicians of the* world.

Now suppose we reverse the order of calculating the radius of curvature by dividing the quadrant of the sphere, and substitute the point of positive infinity as the beginning of our scale of *gradation* of refracting lenses?

To begin this way, we avoid the inharmonious arrangement of taking a medium refracting power, one meter in focal length, as the unit, and we likewise avoid the difficulty of securing a uniform medium as an index of refraction for the construction of our test lenses, and those we prescribe for our patients.

It is a fact, that we do require of the *optician*, a lens having equal angular refraction with our test lens, and we do not require a specified medium out of which to construct the lens prescribed for the patient; it follows, therefore, that we reject the lens measured by focal length merely, as determined by any fixed standard of radius in the grinding tools, and require the crucial test of refracting power. Then, let us so determine our scale as to begin with parallel light, and denominate the refracting media according to their power to deviate that light in angular terms of minutes and degrees. The greatest confusion results from the common habit of writers and practitioners using the denominator of the fraction of the radius as synonymous with so many inches of focal length. It is just as common to observe practitioners using some of the cheap imitations of Snellen's test types, not one of which have either corresponding size or form of the original. I have measured the letters in a large number of so-called reprints and found none of them even approximately like Snellen's. Tests of acuity of perception and angle of refraction in the eye must always correspond, but this can never be possible without correctly graded test lenses, correctly graded test objects, and apportionment of distance in terms harmonious with the mensuration employed in grading the angular distances of test objects, and refraction of the test lenses. Neglect of these essentials impairs the value of nearly all the published statistical tables of clinical observations on all the varying forms of ametropia.

WHAT MAY BE CONSIDERED NORMAL CORNEAL ASTIGMATISM? FROM KERATOMETRIC MEASUREMENTS OF THREE HUNDRED EYES.

Read in the Section of Ophthalmology at the Forty-third annual meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY H. V. WÜRDEMANN, M.D.,
OF MILWAUKEE, WIS.

Keratometry is now considered an essential to the examination of the ocular refraction. As the principal seat of astigmatism is in the cornea there can be no doubt but that the measurement of its curvature is both time and labor saving; and in the near future this fact will be appreciated by every reputable ophthalmist. Correction of refractive errors is the most scientific portion of an oculist's work and cannot be done properly without several means of objective examination.

The ophthalmometer of Javal and Schiötz is conceded to be the most practical instrument for the estimation of the corneal curvature. In the accompanying instructions,[17] in treatises and text books, the corneal is taken as equal to the whole astigmatic error. In 1882 Javal reported[11] that in the measurement of 100 eyes in 96 per cent. the corneal corresponded exactly with the total astigmatism. His associate Nordensen[16] followed later with a report of several hundred more, giving the same average. Since that time this statement has been accepted by most writers.

In 1889 Swan Burnett said[3] that his experience with Javal's ophthalmometer tended to substantiate this although his percentage of difference between the total and the corneal astigmatism was greater. *A few months ago the same author wrote*[4]: "It is a fact that we seldom find a cornea without a measurable degree of astigmatism." Normal corneal astigmatism he would place at .25 or .50 D. according to the rule. G. Lindsay Johnson says[13] *that the majority* of persons possess a corneal astigmatism of less than .75 D. Bull finds[2] an astigmatism of from .25 to .75 D. with the rule in 80 per cent. of his cases. Doubtless *many others** *have* noticed the disparity between the corneal and total *measurements but* have not published their observations. However this may be it seems marvelous that the statement of Javal has *gone so long unchallenged*.

The usual directions for keratometry with the ophthalmometer are: After finding the direction of the principal meridians to carry the movable plaque toward the stationary *until the images* touch and to judge of the degree of the astigmatism, after turning to the meridian of less refraction, by the number of overlapping steps.[17]-[3] This method is open to the objection of *inaccuracy in that* the *personal* equation of each observer admits of an error which may amount to .50 or 1.00 D. It will do very well for rough work but closer results may be obtained, by first approximating the plaques and finding the direction of the astigmatism, then moving the stepped plaque until the images of the first two *black interspaces* are equal. It is objected by Weiland[21] that the refracting quartz prism of the telescope is not achromatic, so that the edges of the images are not sharply defined, making it impossible to get accurate contact. One can more accurately estimate the size of two black objects than judge when two white surfaces exactly touch. Of two equal squares, the one white on a black back-ground, the other black on a white back-ground, when contrasted the former appear larger. The edges of white objects when approximated appear to merge into each other before they actually touch. The refractive values should be read off on the arc, and the differences of the principal meridians noted, as was suggested by the inventors.[12] For accurate determination of the central astigmatism it is essential for the visual line of the subject to exactly coincide with the optical axis of the instrument. I usually request the patient to steadily observe the reflected image of his own eye in the center of the objective. Such varying reports on the relation of the keratometric to the other measurements as given by Chibret,[6] Bull,[2] Burnett,[4] Story,[18] Ostwalt[18] and others may be accounted for by the personal equation of each operator and by the manner in which the examinations were conducted.

---

* After this article was written I came across the following by a writer in an English ophthalmic journal. He published the astigmatism found by the ophthalmometer in 139 eyes, and in a parallel column the cylindrical lenses *finally agreed* upon as the proper ones, after comparison of results obtained from the ophthalmometer, test lenses, ophthalmoscope and retinoscope. In 62 eyes he claims that the ophthalmometer indicated exactly the true amount of astigmatism. In 14 the discrepancy was but .25 D., and in 26 it was a whole *diopter* or over, the
D. He says that in many cases in which the
ylinders were not prescribed. John B. Story,
vol. x, No. 117.

Astigmatism is present at each *point* on the corneal surface where the refraction of the meridians is unequal. Thus we may not correctly speak of "astigmatic zones" as is doneby Sulzer.[19] As a rule we recognize, for practical purposes, only the central astigmatism. This is located at the intersection of the visual axis (which may be considered the same as the line of fixation), and the cornea. (See Fig. 1.) Five degrees on either side of the fixation point usually serve for all purposes of the visual act. If this area be free from aberration we say that the eye is non-astigmatic.

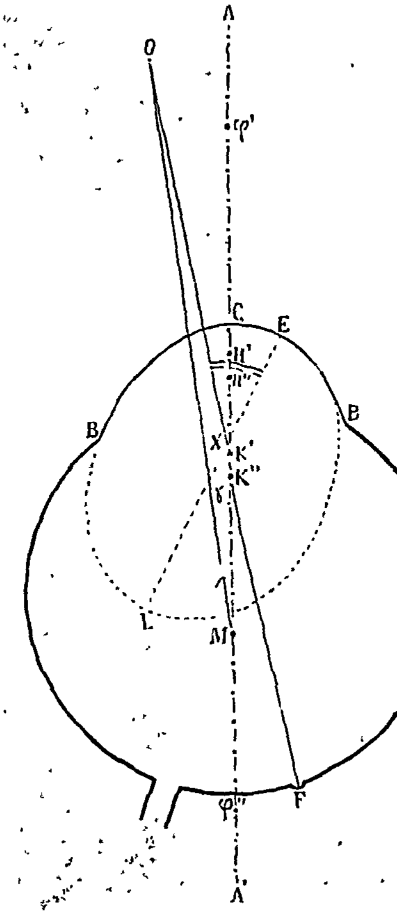


FIG. 1.—Angles alpha and gamma. (Landolt.)[14] A A, optic axis; O F, visual line; *O M, line of fixation*; E L, *major axis of corneal ellipse.* The line of fixation does not correspond with the optic axis, but forms the angle O M A, angle gamma, nearly equal to the angle O X A, formed by visual line with optic axis. O X A may be considered as the angle gamma. The visual line does not pass through the summit of the corneal curve E, but forms with the axis of the cornea E L, the angle O X E, the angle alpha.

All corneæ are highly astigmatic in the periphery, and unless the visual axis bears an unusual relation to the axis of the cornea, their centers are moderately astigmatic. In most cases the curvature of the vertical diminishes more rapidly than that in the horizontal meridian. Thus in certain subjects we find central astigmatism with the rule, and at five or more degrees away from the visual axis it is against the rule. Fig. 2 represents the corneal measurements of an eye in which all other forms of examination failed to show the slightest ametropia.

The refractive values were obtained by causing the subject to look intently during the examination at points 5° removed from each other on the ophthalmometric disc along each meridian until the limits of the cornea were reached. (With a refraction of 40.00 D. this arc equals 0.7369 mm.) It will be seen that I have divided the surface of the cornea into zones, as was suggested by Aubert,[1] but with a modification of his plan. At 10° to 15° about the *corneal* axis (not the visual centre as Aubert puts it), the curvature rapidly flattens, dividing the surface into two true zones, the polar and peripheral. From measurements of a number of subjects I find the former ellipsoidal, its long diameter approximating the general astigmatic axis. The optical portion of the cornea does not accord with the polar zone. It is limited by the angular aperture of the pupil, which even when very wide may be considered to extend about 17° on either side of the center. In this case the center of the pupil corresponds approximately to the optic axis. The shape of the optical zone depends upon the form of the pupil, being usually ellipsoidal, with the long axis within 20° of the vertical. The peripheral portion of the cornea is bounded by the limbus, and may be called the scleral zone.[1] The visual center is usually found in the nasal quadrant of the optical zone, its position depending upon its relation to the optic axis. This is determined by a decentration of the crystalline.[19] In the examination of twenty-two eyes Sulzer found considerable variance of the pupillary center to the axis of vision. (See Fig. 3.) The amount and kind of astigmatism is influenced by the relative position of the visual axis to the different quadrants of the polar zone. For instance, if in Fig. 2 the visual line had passed 5° more to the nasal and lower portions of the optical zone, there would have been no central corneal astigmatism; if 10° higher, it would have been against the rule. In high myopia the angle gamma may be negative, the visual axis will then pass through the cornea to the temporal side of the axis of rotation. The two may coincide in lower degrees of myopia, or in hyperopia the visual line may be even more to the nasal side.[7] In this subject the angle gamma was positive, the optic axis being about 4° outward and 1° downward from the visual center.

The amounts of the normal lenticular, and proportionately that of the normal corneal astigmatism, appear to be greatly influenced by the size of the angles gamma and alpha. This factor is also an important element in modification of astigmatism from other causes. At a future time I hope to report more fully on this subject. In the diagram (Fig. 2) there is shown a central astigmatism of .50 D. in the vertical meridian. We see that the astigmatism remains with the rule within an area of 5° around the visual center. At the lower and inner portions of the optical zone the cornea is non-astigmatic, as is shown by the shaded area on the chart.

On account of the more rapidly diminishing curvature in the vertical meridian, in the scleral or peripheral zone the astigmatism becomes *against the rule*, until at the superior margin of the cornea it amounts to 3.00 D., and at the lower border is 5.00 D. against the rule. On the contrary, in the horizontal diameter the astigmatism gradually increases *with the rule*, being at the nasal limbus 7.00 D. and at the temporal 9.50 D. with the rule. Outside of the optical zone the axes of the principal meridians deviate from 90° and 180°; these axes in places are not at right angles to each other. This is due to the irregular curvature of the scleral zone. In the horizontal and oblique meridians we find less variation. Within the optical area of corneæ with oblique central astigmatism we may find the axes to vary in a surprising manner.

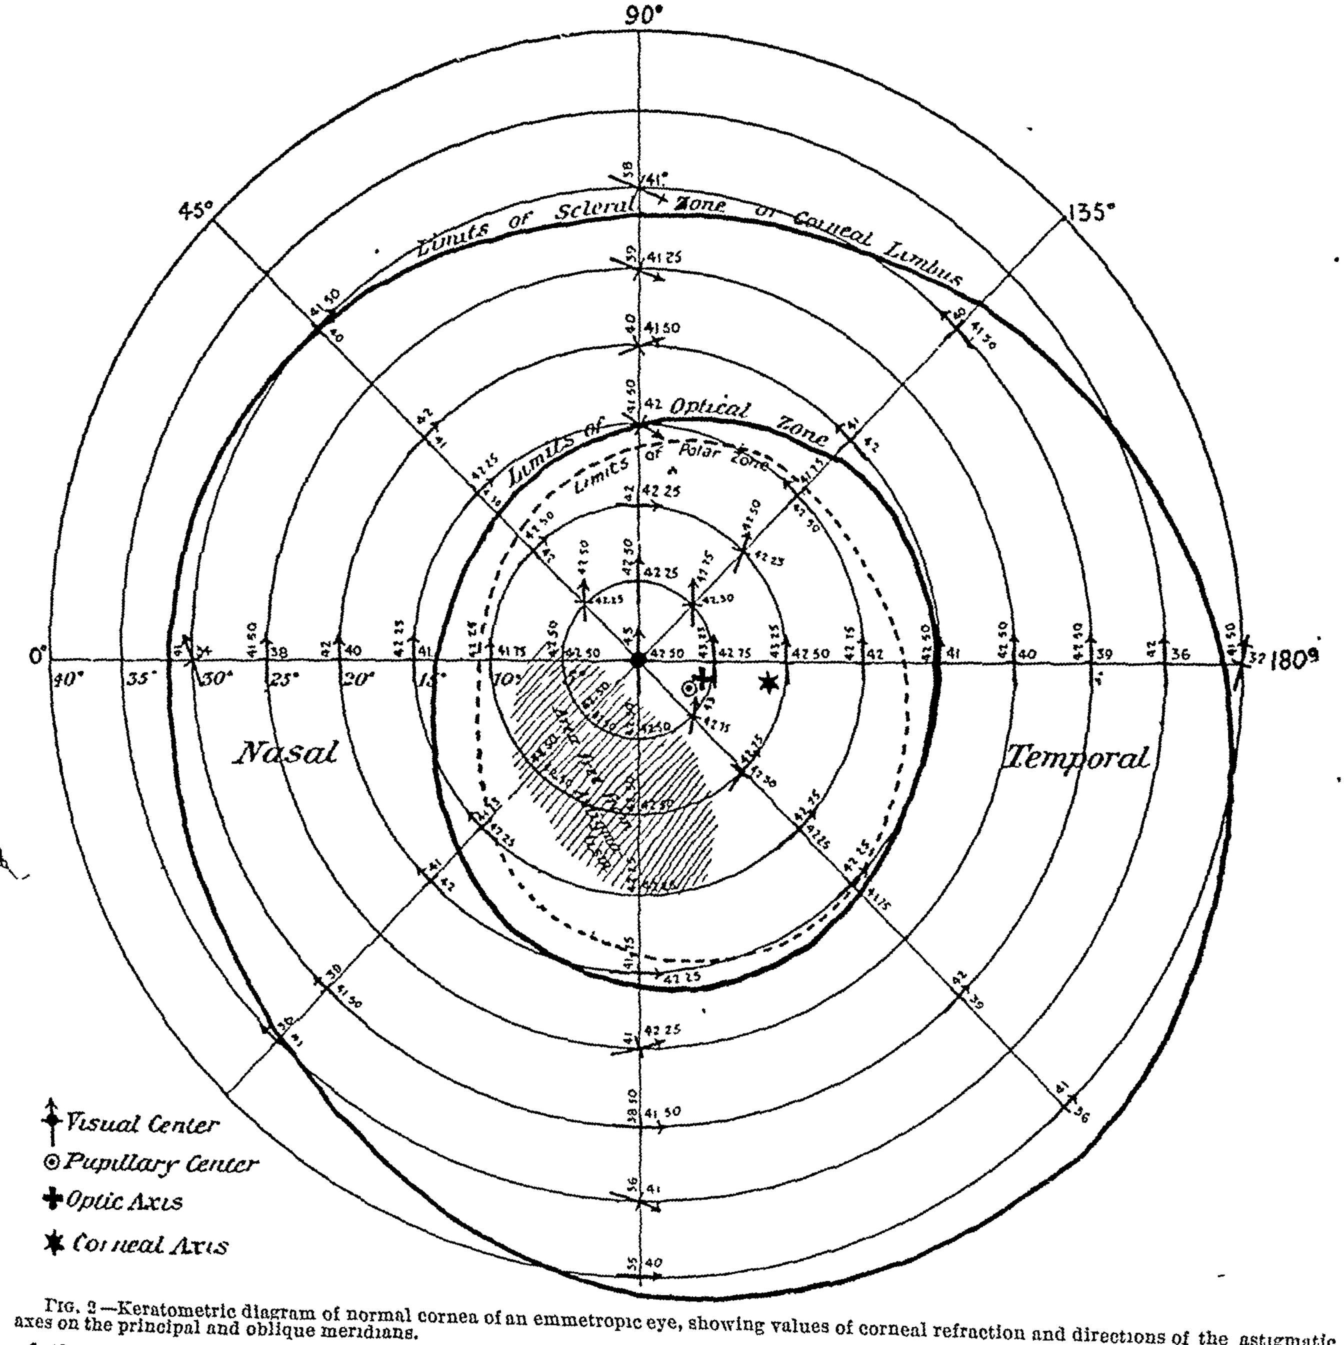

Fig. 3.—Keratometric diagram of normal cornea of an emmetropic eye, showing values of corneal refraction and directions of the astigmatic axes on the principal and oblique meridians.

In Fig. 4 there is shown the optical zone of a cornea with central astigmatism of 3.25 D. at 30°. Five degrees down on the vertical meridian there is 3.25 D. at 75°, and the same distance up, 1.00 D. at 135°. Outwards it is 4.50 D. at 60°, and inwards 3.50 D. at 75°. All of these measurements are within the area used for distinct vision. At 10° in all directions from the center of vision the astigmatic axes tend toward the direction of the meridian upon which measured, at 15° away almost coinciding. It is seen that this corresponds to the emmetropic eye in that the curvature diminishes more rapidly in the vertical than in the horizontal diameter, making the peripheral astigmatism *against* in the vertical and *with* in the horizontal meridians. These changes in the directions of the principal meridians (denominated "meridional astigmatism" by Jackson),[9] show the physical impossibility of bringing up the visual acuity to the normal in most cases of oblique astigmatism. In this subject the optic axis was found to be 2° obliquely downward and outward of the visual center, and the corneal axis 5° diagonally downward in the opposite quadrant.

Degrees of corneal astigmatism of three or four diopters may be produced by the visual line passing eccentrically through the cornea, and I am convinced that this is one of the principal factors in its production. It is true that many corneæ are congenitally deformed, and that others become so through the effects of inflammation or ulceration. The defect may also be due to the mechanical effect of the recti muscles or some extraneous cause. I have seen 5.00 D. against the rule appear *after a cataract* extraction and 2.00 D. after an advancement of the recti muscles, and the same has been noticed by others.[5] The amount of monochromatic aberration in the horizontal meridian of the cornea has been worked out[8] by Prof. Harkness to amount to about 1.00 D. in a pupil of 4 mm. In his report he said that the data he could procure for the vertical meridian was too meager to allow of a satisfactory result. I doubt not but that this would be found greater in the vertical meridian, for my measurements tend to show that the vertical is less regular than the other meridians. These changes must be considered a portion of the irregular astigmatism of the eye.

Between the dates of February 1 and May 20 of this year, my associate, Dr. J. S. Barnes, and myself have been preserving the corneal measurements taken by the ophthalmometer of Javal, in selected cases, with the view of establishing reliable data upon which an estimate of the difference between the total and the corneal astigmatism could be made. During this period we have recorded in all 300 eyes, of which there were 63 emmetropic, 52 simple hyperopic, 8 simple myopic, and 177 eyes with total astigmatism for which glasses were prescribed. Of the latter there were 119 with the rule, 27 against, and 31 with the axis oblique—making 177 astigmatic and 123 non-astigmatic eyes. These were examined by the ophthalmoscope, skiascope, ophthalmometer and the subjective tests (90 per cent. of the ametropic eyes being examined under homatropin or atropin), for the detection of visual error. Of the whole number, in 279 (93 per cent.) the corneal differed materially from the total astigmatism, being equal in only 7 per cent. All of the emmetropic eyes showed a difference, from a little less than .25 to .75 D. Of the simple hyperopic but 4 per cent. had the same; of the myopic all were equal; and in the eyes with total astigmatism 19 (10.75 per cent.) had the corneal equal to the total error, while in 158 cases (89.25 per cent.) there was a difference. In two cases the disparity between the corneal and total measurements was sufficient to change an error shown by the ophthalmometer as *with* the rule to *against* as given by the other tests. All of the emmetropic, myopic and *hyperopic eyes had central corneal astigmatism.* The number of simple myopic cases was too small to formulate any rule, but we may safely say that emmetropic and simple hyperopic eyes are seldom or never free from central corneal astigmatism. Of 177 astigmatic eyes there were 14 without corneal astigmatism, being pure lenticular cases, making my percentage of total astigmatic cases without corneal error to be but 8 per cent.

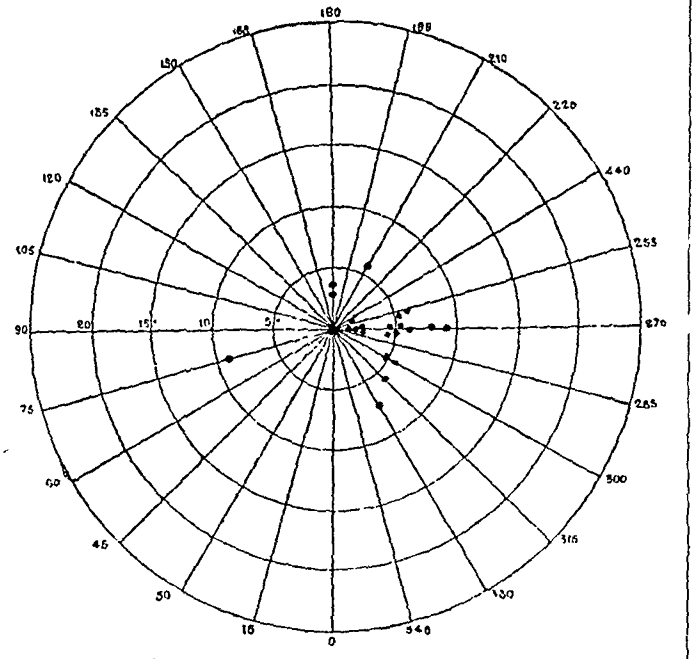

FIG. 3.—The black points indicate the pupillary centers of 22 eyes The visual line passes through the center of the figure. The left side of the diagram corresponds to the nasal side of the eye. (Sulzer.)[19]

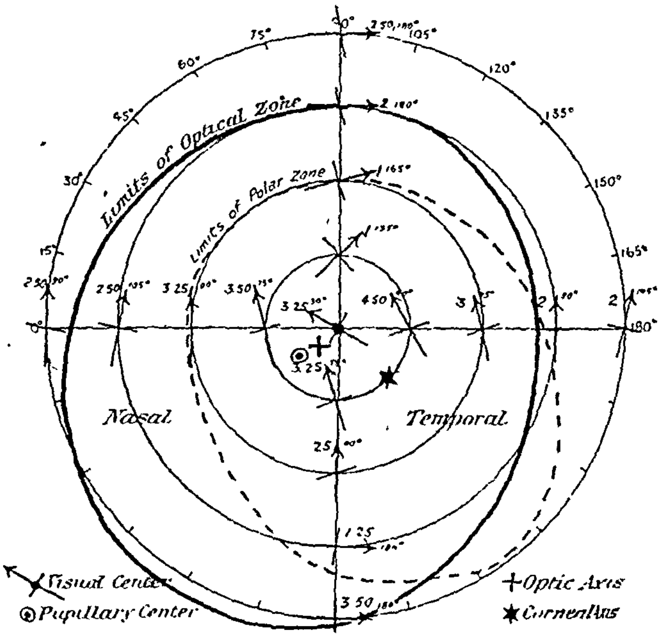

FIG. 4.—Optical portion of a cornea with central astigmatism of 3.25 D. at 75, showing variations in the axis of meridional astigmatism.

The following table shows difference between the amount of astigmatism found by the ophthalmometer and that agreed upon by other methods of examination:

TABLE SHOWING DIFFERENCE BETWEEN CORNEAL AND TOTAL ASTIGMATISM IN THREE HUNDRED EYES.

CORNEAL ASTIGMATISM.

Total Refraction.	Equal.	Greater.					Less.					Totals.
Amounts	0	.25	.50	.75	1.00	over	.25	.50	.75	1.00	over	
Emmetropia	...	20	34	9	..	...	..	..	..	..	...	63
Hyperopia	2	11	26	7	4	2	..	..	..	..	...	52
Myopia	...	3	4	1	..	...	..	..	..	..	...	8
As. with	9	17	50	35	6	2	..	..	..	..	...	119
As. against	4	..	..	..	..	...	7	10	1	1	2	25
Tot. against Cor. with	...	..	2	..	..	...	..	..	..	..	...	2
Ax. 45°–135°	...	3	2	1	..	...	..	..	..	..	...	6
Ax. 15°–165° 75°–105°	3	3	3	2	3	1	..	..	4	..	...	19
Ax. 30°–150° 60°–120°	3	1	1	1	..	...	..	..	..	..	...	6
Totals	21	58	122	56	13	5	7	10	5	1	2	300

In adults there was usually a *surplus* of .50 D. when the astigmatism was *with the rule*, and when *against the rule*, the corneal value was the same amount *less* than the total error. In children the average difference was .75 D., and in old people .25 D. Most of the cases where the corneal tallied with the total astigmatism were found in the elderly; when the meridians are oblique the measurements more nearly agree. This should be accepted as a very general statement, as the astigmatic aberration is modified both by the amount of lenticular decentration and the kind of general ametropia. In myopia the angles alpha and gamma may be smaller or even non-existent, in hyperopia larger; thus in the former the normal corneal and lenticular astigmatism is less, and in the latter larger. There is no doubt in my mind but that this difference is neutralized by a corresponding lenticular astigmatism of the opposite kind. This has been mentioned hypothetically by others, but I have never yet seen a refutation of Javal's statement relative to the identity of the corneal with the total astigmatism. Normal lenticular astigmatism is always *against the rule*. It has a definite relation to the size of the angle gamma, having its origin in the oblique position of the lenticular refracting surfaces to the visual line D. The decrease in difference between the total and corneal errors in old subjects, may perhaps be explained by senile changes in the lens structure increasing its refraction. I do not believe in the production of "spastic" lenticular astigmatism by irregular or partial contraction of the ciliary muscle, although cases have been reported[15] in[10] which the total astigmatism has been increased under full mydriasis. I believe with Sulzer[19] that when the size of the pupil is increased beyond the normal, as by atropin, that the zone outside of 5° from the visual axis participates in the ocular refraction, and in cases where there is a marked difference between the error of this and that of the center, a change may take place in the amount of total astigmatism under mydriatics according to the degree of corneal asymmetry. I allow that "tilting" of the lens[2] exists[15] as a cause of lenticular error, but consider the explanation here given a preferable view of *normal* lenticular astigmatism. The few cases where the axis of the total astigmatism varied from that of the corneal may perhaps be explained by obliquity of the lens, as suggested by Tscherning.[20]

It is generally held[3 7] that much of the irregular central astigmatism of the eye lies in the lens. I would ascribe some of this to the cornea as well. In fully a quarter of my own measurements the directions of the principal meridians but a few degrees removed vary from that of the visual center. Even in the optical zone the principal meridians may not be at right angles to each other. (See Fig. 4.) In consequence of this irregularity it is impossible to fully correct an astigmatism by cylindrical lenses, and such a correction must always be considered an approximation.[19] There is a certain amount of amblyopia due to astigmatism and this is in proportion to the amount of corneal asymmetry.[15]

In such an imperfect and variable an instrument as the human eye, where in one person of sensitive nervous organization a total astigmatism of .125 D., against the rule, gives rise to eye-strain, while in another doing the same amount and kind of work an astigmatism of even 2.00 D. is tolerated with impunity; where shall the line be drawn? What may be considered normal corneal astigmatism? I regard that amount of corneal astigmatism as normal which is neutralized by a corresponding lenticular astigmatism of the opposite kind. This is equal to the difference between the total and the corneal measurements, which may be considered a corrective effort on the part of nature in neutralizing a certain amount of lenticular error. In the use of the ophthalmometer in glass fitting I am prepared as a general rule to deduct .50 to .75 D. from its readings in children and .25 to .50 D. in adults when the meridian of greatest refraction is vertical, and when this is horizontal to add the same amounts in estimating the total astigmatic error. When this meridian is at 45° or 135° the corneal and the total errata will be about the same; when at other angles a greater or less varience is to be expected according to the relative nearness of the principal meridians to the vertical or horizontal. Where no central corneal error exists I expect to find astigmatism against the rule.

Discussion.

Dr. Henry D. Noyes, of New York:—I am able to say something with reference to the objective determination of astigmatism from seven years' experience with Javal's ophthalmometer. I have looked at not less than five thousand eyes and have made records of what I have seen. I shall simply speak of a few practical points which have been elicited by the very accurate description given by the reader of the paper. The irregularity of the form of the cornea is very well known and it is equally well known that it does not yield itself to any proper mathematical formula. It is also true that only the central portion is available for accurate vision and that has two practical corlolaries. In the first place it means that the vision which we can expect to obtain by the operation of iridectomy must necessarily be imperfect because of the irregularity of the cornea, provided the central portion is excluded. If the central portion remains in use, it does not follow that the irregularity of the curve will have a great depreciating influence upon vision. This is demonstrated by the results of extraction of cataract with or without iridectomy, and it is a fact that equally good results may be found after extraction of cataract with iridectomy as when no iridectomy has been done. A notable instance of this came under my notice not long ago. A man 50 years of age had had extraction performed by a friend and his visual acuity was 20-18. I found on examination of the cornea that there was astigmatism of about 1 D., and when that correction was added to his glasses his vision rose to 20-12. The difference is small but it shows that the central portion of the cornea was by all odds the dominant portion.

The value of the ophthalmometer is higher than is generally supposed. For example, Javal said that it gave the total error within about 1 D., but my experience is that it gives you the lens to within about .50 D. Many times it gives the exact error and the glass required so far as the cylinder is concerned. This has been illustrated to me many times and a case occurring within a week is in point. This individual had worn cylinders for two years but they had been changed at different periods. The ophthalmometer showed in one eye astigmatism of 1.5 D. and in the other 1.25 D. He had never worn cylinders of more than .50 D. He would accept a cylindric correction amounting to what the ophthalmometer gave provided the correction consisted of both a plus and a minus cylinder. He was an example of mixed astigmatism. Mixed astigmatism has been shown to exist in a larger percentage of cases than was formerly supposed.

It is also true that vision, when the astigmatism is found in the oblique meridians is rarely made normal, whether these meridians have a symmetrical relation to the median plane or not.

Another fact that is brought out by the examination with the ophthalmometer is that the principal meridians of the cornea are, in some instances, not at right angles with each other. One may be at 90°, while the other is at 30°. One may be at 80° and the other at a point less than a right angle to the first. The consequence is that you have to adjust the axis of the cylinders according to what the patient will accept, and not according to what the ophthalmometer shows to be the true condition. In other words the determination of what the patient must wear is a practical question and is to be determined by experiment. The value of the ophthalmometer is to show the lines within which the experimentation must proceed. With the knowledge which a little experience gives and with a careful observation of the facts which the ophthalmometer has shown, you will rarely fail to discover any important error.

Another point is that the use of the ophthalmometer has greatly diminished the necessity for a mydriatic. The employment of a mydriatic I am confident should be limited to cases in which the amount of pain and severity of the subjective phenomena make you feel that an anodyne must be applied, and here the atropia is employed rather as an anodyne than for the purpose of enabling you to determine the refractive error.

In my work I rely chiefly, first, upon the ophthalmometer, second, upon direct examination with the ophthalmoscope with the glass determined by the ophthalmometer placed behind the mirror, and then I go to the test box to ascertain what can be done to bring the acuity of vision up to the normal.

These are some of the practical points relating to this subject of astigmatism, and which enable us by proper objective methods to make the subjective examination less trying to the physician and patient than was formerly the case.

Dr. Samuel D. Risley, Philadelphia:—In entering upon a discussion of this important branch of ophthalmology, I should like to emphasize a significant remark made by Dr. Noyes, that after the use of the ophthalmometer the glass which is to be prescribed is the result of testing rather than of the scientific data obtained by the ophthalmometer. This is strictly in accordance with my own experience. The glass to be prescribed is the one selected by the patient as giving the best acuity of vision.

In reference to the use of mydriatics. In my experience, the majority of persons who come with asthenopia, fall in the category mentioned by Dr. Noyes, that is, they have pathological states of the chorvia and retina which call for the use of the mydriatic for its therapeutic effect. Moreover in these cases, a mydriatic is required to get at anything like accuracy in estimating the error of refraction. Without it, different results are obtained on successive days. If the mydriatic is used the results are the same at different examinations, and if the mydriatic is continued, vision, which at first was below normal, because of the accommodative retino-chloridal irritations and turgescence, will come up to the normal standard, as this condition subsides under the enforced rest and sedative influence of the drug.

Dr. G. C. Savage, Nashville, Tenn.:—Astigmatism can be corrected either by lessening the curvature that is too great, by means of a concave cylinder, or increasing the curvature that is too small by means of a convex cylinder. I am on the floor to advocate the claims of the mydriatic. In many cases the patient will take a concave lens in preference to a convex lens, when actually the convex lens is the one that is needed. The ciliary muscle is often unruly and I am not willing to refract a case in a young person where this muscle is allowed to run riot. There is no harm in using a mydriatic. There seems to be a disposition to discard its use and that is what the people want. The mydriatic does no injury, while it enables us to do accurate work. Without a mydriatic I should not be willing to undertake the refraction of the eyes of a young person.

Dr. Eugene Smith, Detroit:—I am one of those who find it unnecessary to use a mydriatic as much as formerly. With the ophthalmometer, the retinoscope and the ophthalmoscope, I have, within the past two or three years, found myself using mydriatics more and more seldom every month.

In regard to the peculiar axis in using the ophthalmometer, I find that sometimes we are careless in letting the patient twist the head from the one side to the other and we do not find the same axis in the two eyes. When I find that the axes are inclined to be parallel or do not agree, I frequently do the work over and find that the mistake was my own and not due to the differences in the two eyes.

I have so far heard nothing particularly said in regard to retinoscopy or skiospy. These are not depended upon as much as they should be. Dr. Noyes says that he uses the ophthalmometer, then the ophthalmoscope and then goes to the test glasses. I go further, I take the ophthalmometer, then the ophthalmoscope and then the retinoscope, but in the large majority of cases I do not find it necessary to use a mydriatic in retinoscopy. Some think that they must use it in every case. With me, its use is decidedly the exception rather than the rule. I also use the direct method with the ophthalmoscope after the method mentioned by Dr. Noyes of fitting the cylinder into the ophthalmoscope. I however, use the optometer of Cooper, of London. I find it superior for retinoscopy.

In regard to what is normal astigmatism, I should consider normal astigmatism to be that degree which produces no trouble, that is where you do not know whether it exists or not. Where a patient comes with astigmatism, no matter what its degree, if there is asthenopia, I regard that astigmatism abnormal. In the majority of cases where it is corrected and there is no abnormal muscular condition, the patient gets well of the asthenopia.

Dr. A. A. Hubbell, Buffalo, N. Y.:—I have used the various objective methods of measuring astigmatism. I have great confidence in retinoscopy, and during the past few years I have also used the ophthalometer and found it a most valuable aid. My experience has taught me, however, that the higher the degree of astigmatism we find with the ophthalmometer the more should we under-correct it, in prescribing cylindrical glasses. In a conversation recently with Javal, he told me that he decreased the strength of the cylinder proportionately, the higher the amount of astigmatism shown by the ophthalmometer. If he found astigmatism amounting to 1 D. to 1.25 D. he would expect to prescribe O. 50 D. to O. 75 D.; if he found 3.00 D. he would prescribe about 2.25 D. and so on. I have noticed recently[1] an article in the Philadelphia *Medical News* by Dr. Willman, in which some mathematical calculations have been made, showing the errors of Javal's ophthalmometer, and these errors nearly correspond with the differences which Javal himself made between the cylinders used, and the astigmatism indicated by his instrument. Javal has tabulated the cylinders that should be prescribed in the various readings of his instrument in his work on ophthalmometry.

Dr. H. V. Würdemann, Milwaukee:—We cannot have too many means of objective examination. In my opinion the ophthalmometer is our most exact instrument in the search for astigmatism except in favorable cases under a mydriatic with the skiascope.

One of the gentlemen spoke of normal astigmatism. My subject was normal *corneal* astigmatism, that is the difference between the total astigmatism and the corneal astigmatism.

In the lower grades of corneal astigmatism in the emmetropic, hyperopic or myopic eye, the ophthalmometer will give too much or too little according as the astigmatism is with or against the rule. In the higher grades, the ophthalmometric measurements are greater than the glasses prescribed. For instance if this is 3.5 D. the ophthalmometer may give much more than that amount. I have ascribed this to my indisposition to fit fully correcting lenses in hypermetropic astigmatism and I generally under-correct. I allow a certain amount for the wishes of the patient, averaging the results of all the tests, but do not place too much stress upon his preference when against the objective tests.

LEG ULCER.—Dr. Weismueller praises the action of a dusting powder thus composed:

[1] Note by the author. Dr. Hubbell probably refers to the article by Carl Weiland, M.D.[21]

A METHOD OF EXAMINING THE EYES OF SCHOOL-CHILDREN.

ASED ON THE STUDY OF THREE HUNDRED AND FIFTY-SIX BOYS IN THE WILLIAM PENN CHARTER SCHOOL.

ad in the Section of Ophthalmology at the Forty-third annual meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY B. ALEX. RANDALL, A.M., M.D.,
OF PHILADELPHIA, PA.

Threadbare as this subject may appear to anyone ho, without special interest in it, has noted the apearance of hundreds of papers on the matter, and as, perhaps, been disgusted at the wide discrepncies of views and results which they too often reeal; it is, nevertheless, one of great importance to s, as citizens and ophthalmologists, and it is likely demand more, rather than less, attention in the ture. All its aspects have claims upon our interest nd study, but many of them belong to the Section n Hygiene and State Medicine rather than to the phthalmic Section. I wish here and at this time, formulate some views as to the methods of invesigation which have been impressed on me as best by dozen years of study, in the hope that any future nvestigators may profit, as they too rarely have in he past, by the experiences of their predecessors.

Few will question that the school should elicit and evelop the mental aptitude of the scholar,revealing, nd if possible, correcting his weak points; and the ime is past when its relation to the physical condiion can be neglected. Nor is it enough that *damage* o the individual during the educational process hould be avoided—that the "overburdening of the cholars," of which so much has been said, should be revented from producing "school myopia", scoliosis, r the many other ills more or less fairly laid to its harge. Physical education and development is demanded as a part of the school régime; and the cholar ought to be made a "better all-around man," as well as mentally drilled for a special career, if he shows aptitude or has decided on one already. At the least, any disqualifying physical infirmity should e discovered, and opportunity given to remedy it or avoid its effects. Knowing that four per cent. of all boys are more or less color-blind, it is our duty to find out which are the unlucky ones and not leave them to discover it in some disastrous fashion. Time and again I have known candidates for the navy, who were exceptionally good scholars, possessed of splendid physique, coming long distances, and perhaps wasting much time and money in special preparation, only to be incontinently rejected as color blind,and sent home as completely discomfited as though they had been proved imbecile.

It is a matter for great congratulation that the subject of the physical education of the pupils in the schools is now receiving growing consideration. Most colleges have placed their gymnasia and athletic sports in the care of someone more or less fitted to restrain, as well as to promote, the exercises of the scholars. Scientific methods of physical examination and development have made increasingly good results possible; and in most of these institutions systematic exercise is reducing the number of the weaklings, guiding and controlling to good purpose those aspiring to be athletes, and, still more important, is raising greatly not only the standard of muscular strength, but also the good health and mental capacity of the main body of the students. Similar results are being gained in the public and private schools, and will grow still more common as the advantages become more manifest and they vie with each other in their efforts to attract pupils.

Such a semi-annual physical examination, made in the William Penn Charter School of Philadelphia, last Autumn, furnished the results which form the text of my present paper. It was made by the Director of Physical Education as to all details of height, weight, girth of chest and limbs, and the dynanometer and spirometer results; and by a physician, Dr. Spenser Trotter, as to the medical aspects, such as the auscultation of the heart and lungs, and the condition of the eyes and ears. This latter part I undertook for him, as he was in doubt as to the best practicable methods; and it is in the belief that an account of it may be of value to others having such work to do, that I now make this report.

Every such examination is fraught with great difficulties. A certain number of parents will be found hostile to it, regarding it as an invasion of their American liberties and as prompted solely by sordid motives on the part of the examiner. Great prudence must be used in answering any of the questions, general or personal, which are asked by the scholars; and no report should be made, as a rule, except the official one to the school authorities. Much time and labor must be expended upon it, with the consciousness of having done useful and scientific work as the only reward; and the man who begins enthusiastically is apt to find the task very wearisome, and the sacrifice of time and energy a very severe one, before it reaches its close. For this reason a clear understanding of what should be learned, and a knowledge of the great shortcomings of the many examinations thus far made, are prerequisites to the undertaking. Too extensive a work should not be attempted; while on the other hand, although hundreds of thousands have already been examined, there is need for much further and better study, especially of small groups, repeatedly investigated.

My purpose was to obtain results that should be practically and scientifically valuable. Subjective tests, therefore, constituted but one part of the investigation; and, as time was an important question for all concerned, the methods to secure systematically full and accurate results were very important. A critical study of nearly every one of the two hundred or more examinations which have been made, and some previous experience in applying the ideas derived from them, as to what is desirable and practicable, have convinced me of the necessity of some tests, and the worthlessness of others commonly employed. The method pursued, closely similar to that used by Risley in 1879–80 and by myself in 1884, and now recommended, is as follows:

An accurate test card and astigmatic chart, such as Wallace's, are placed 6 meters away from the seat to be occupied by the pupil, well illuminated by an argand burner a half meter distant, which is hid from view by a black screen, perforated so as to give a point of light for muscle tests, and quartered with white lines to indicate the amount of any deviation found. Behind the pupil another argand burner furnishes light for tests of the near vision and for ophthalmoscopy and retinoscopy. The room is otherwise darkened by drawn shades. The Maddox prism or rod, a "prism mobile," test glasses, Holmgren worsteds, ophthalmoscope, etc., must of course be within easy reach. Well-planned blank forms should be used for recording systematically and completely every result of the study; and much time and labor can be saved by a competent assistant, but most valuably as a mere clinical clerk, leaving all actual tests to the examiner himself.

Working upon this plan, the distant vision is first determined, each eye being screened in turn by a black card, and the subjective recognition of astigmatism tested upon the radiating lines, which should be the parallel bands of Green, not the simple radii. The muscular balance is then tried for the distant point of light, and any deviation measured by reference to the lines upon the screen or by the interposition of the prism mobile. The near vision for fine type, usually D. = 25, is then tried and the punctum proximum carefully noted, with the p. r. in myopia, etc. The Graefe test with a very fine dot-and-line, or the simple test which I have advocated (Trans. Amer. Ophth. Soc., 1889, *Medical News*, September 7, 1889), of estimating the amount of movement of the eye from a position of rest under cover to that of fixation upon the fine object to which the fellow eye has been directed, will give prompt measure of any insufficiency of convergence, etc. The ophthalmoscope, in the upright image, gives the details of the eye-grounds, the condition of the media and the apparent refraction. The retinoscopy, with the plane mirror from 4 meters distance, gives delicate qualitative indication of the refraction, aided at need and made quantitative by a glass or two from the test case; and the test of distant vision, with any glass apparently required, or with that worn, often furnishes valuable data. The latter is quickly measured by neutralization, and when and how it was obtained learned by a question or two. A moment's use of the pen gives rude but valuable sketches of any anomalies of vessels, conus, etc.; the field can readily be taken in any case calling for it; the general and the ocular condition of health can be learned, with any note of inflammation of lids, conjunctiva or cornea, deviations of the eyes, apparent or actual, nystagmus, etc. A moment spent over the worsteds (on which each eye should be separately tested, and better by daylight), and unless the ophthalmometric measurements are desired, the examination may be terminated. In short, the entire examination usual in the office work of the careful specialist can be carried out; as it should be, if we are to learn the actual condition of the scholars' eyes—for every careful worker is aware that errors enough are possible even in the fullest and most scrupulously exact first study. Even when recording all these data myself, each examination could be completed in five minutes or less; and an expert observer, with a good clinical clerk, ought to be able to examine twenty or more in an hour.

As to the results of the examination, I shall shortly report elsewhere: it is sufficient to say that the results accord with those of my previous study of the eyes of medical students (Trans. Pennsylvania State Medical Society, 1885), and with the summarized results of all the previous investigations, as critically analyzed in my papers on "The Refraction of the Human Eye," *Amer. Jour. Med. Sciences*, July, 1885, and in the Transactions International Ophthalmological Congress at Heidelberg in 1888. There was a ow percentage of emmetropia, few myopes, hypermetropic refraction predominated, and astigmatism was proved in nearly half the eyes. Color blindness was rare, being found in but nine cases, and there was only one case of retinitis pigmentosa; but a notable group of individuals was found where the conditions demanded prompt reference to their medical advisers for treatment of threatening disorders or the correction of serious optical defects.

Dr. Samuel D. Risley, Philadelphia:—I would urge with Dr. Randall the importance of this thorough and careful examination if the work done is to be of any scientific value. I do not believe that the simple cursory testing of the sharpness of vision and the determination of the manifest refraction by glasses give results of any value when compared with the thorough work suggested by the author of the paper. Unless sufficient care is exercised to secure approximately accurate results the work is practically valueless. Such careful work gives data from which can be obtained the relations of the different refractive conditions to the pathological changes which accompany them. I am glad that Dr. Randall has brought this subject to the attention of the session.

Dr. Francis Dowling, Cincinnati:—I have been much interested in this subject of the examination of the eyes of school children. Three years ago, I commenced a series of examinations in the schools of Cincinnati in order to determine the percentage of nearsightedness among the scholars. The great difficulty is to get the consent of the principals of the schools to put a mydriatic into the eyes of the pupils. In the cases that I examined, I arranged to go on Friday night and drop in the mydriatic so as to have the eyes in fair condition for study on Monday. There was almost a crusade against me for my work. I made a report to the school board, and the paper was referred to the committee on hygiene, and that was the last I heard of it. If we could get the members of the school boards interested, we could do a great deal of good. There are many evils in the way of light, position of the desks, etc., that could be remedied, and a great deal of trouble saved. In one school, the light was so bad that 73 per cent. of the children were nearsighted. I called the attention of the principal to it and he had the desks altered, but after he had given the order the school committee ordered the desks back again to the old position. That is the trouble in trying to get anything like a scientific result.

Among the German scholars I found uniformly about one-third more of near-sightedness than among the English speaking scholars. The German books seemed to be largely at fault in the production of this larger amount of near-sightedness. I suggested to the school board the advisability in the next contract for books, to have the books printed in the latin characters instead of the German. I got most of the German members to come to my view after showing that in Germany most of the text books are printed from latin type.

Dr. B. Alex. Randall, Philadelphia:—I doubt if any further words are needed, as I have probably said quite enough in regard to the general aspects of the question. I hold the belief that this investigating of eyes presumably normal, such as we find in school children, is almost the sole way of understanding what constitutes the usual, if not the strictly normal, refraction of the human eye. It is from the investigation of large numbers in some such fashion that we are to obtain our basis from which to deal with the whole question of the correction of refraction-errors and other conditions which we regard as evils, and to gain a comprehension of other more strictly hygienic questions of school influences upon the eyes of the pupils. But these things should be carried out primarily with the intention of directly helping, guarding and protecting the children under examination, removing if possible the faulty conditions under which they work and picking out those who are unable to stand the pressure which their fellows can safely bear. The school authorities must be furnished with the results; the detailed reports must be made to and for them alone, that, as in the case to which I have referred, the individual results of the examination may be sent to the parents and guardians for them to act on as they see fit. It is through the school authorities that the examinations are to be made and to be utilized. They must be in such form as not to interfere too much with the school work; but we must do our duty in such a way as to get results that will not be worthless and misleading. In none of these cases of color blindness, retinitis pigmentosa, or other serious lesion, or of large refraction errors even with low vision, had the conditions seemed recognized in a previous examination. This is the condition in a large proportion of these examinations; and I fear that it is often so even when undertaken by men professing to be ophthalmologists. I have shown that a fairly complete examination can be made in a period varying from three to five minutes, and I hope thus to remove the excuses for slipshod work and to make clearer the methods of meeting the requirements of these cases.

MANIFEST AND LATENT HYPEROPIA.

Read in the Section of Ophthalmology, at the Forty third Annual Meeting of the American Medical Association, held in Detroit, Mich., June, 1892.

BY EDWARD JACKSON, A.M., M.D.,
PROFESSOR OF DISEASES OF THE EYE IN THE PHILADELPHIA POLYCLINIC, SURGEON TO THE WILLS EYE HOSPITAL, ETC.

It has frequently happened in the history of medicine that to clearly formulate an idea so that it could be practically applied in farther study, and especially in order to enforce it on the attention of others, it has been given more prominence and more definiteness than it really deserved. This I believe has happened with the conception of latent hyperopia. Unquestionably latent hyperopia exists very frequently. But it probably does not exist so frequently, and to the extent that might be inferred from much that is said about it.

For several years I have made it a rule to ascertain as accurately as possible the state of refraction before using a mydriatic, especially in what seemed to be cases of hyperopia almost, or completely free from astigmatism. From my last three years' records of errors of refraction I have sought out all those in which a record was made of the manifest and after the use of a mydriatic of the total hyperopia. The summary of these, including 214 eyes, is presented in the following table:

TABLE I.

Age.	Having no Latent H.	Having Latent H.	Per. cent of H. Latent.	Amount of H. Latent.
15	79%	21%	30%	0.70 D.
20	79	21	26	0.45
25	77	23	24	0.57
30	64	36	33	0.62
35	62½	37½	26	0.41
40	68	32	20	0.31
45	62½	37½	15	0.39
50	53	47	33	0.33

In the above table the first column gives the ages, the second gives the per cent. of eyes in which there was no latent hyperopia, the third column the percentage of cases in which a portion of the hyperopia was latent, the fourth column the average per cent. of the total hyperopia that was latent, in those cases in which any latent hyperopia existed; and the fifth column the average amount in dioptres of the latent hyperopia among those cases in which any portion of this hyperopia was latent.

Before discussing the rather startling facts that this table reveals let us consider for a moment its relations to any similar investigation by other observers. So far as I know the observations most nearly comparable to these are those recorded by Daniels of Berlin (*Centralblatt fur Prak. Augenheilkunde*, July-August 1883; and *Ophthalmic Review* Vol. ii, p. 300) based on the cases presented at Hirschberg's Clinic, measured ophthalmoscopically, most of them by Hirschberg himself. The points for comparison may be indicated by the following table:

TABLE II.

Age.	Proportion of the Total Hyperopia that is manifest.			
	One-third.	One-half.	Two-thirds to three-fourths.	All.
10 or under	85	10	5	
11 to 15	78	18	4	
16 to 20		76		24
21 to 25		68		32
26 to 30		14	62	24
31 to 35		11	63	26
36 to 40			28	72
41 to 45			13	87
46 to 50			5	95
Above 50				100

In this table the first column gives ages; the second indicates the percentage of cases in which the manifest hyperopia was not more than one-third of the total hyperopia; the third column gives the percentage in which the manifest was one-half the total hyperopia; the fourth column, the percentage in which the manifest was from two-thirds to three-fourths of the total; and the last column the percentage in which all the hyperopia was manifest.

Donders (Accommodation and Refraction, p. 239) thought that at twenty years about one-half the total hyperopia was manifest, at forty, more than three-fourths, and at fifty-five, latent hyperopia had ceased to exist. It is interesting to compare these earlier statements with the figures given in columns two, three, and four of table I. The discrepancy between them is startling, and in view of the high scientific attainments of the other observers demands explanation. The data upon which Donders founded his opinion are not given. The basis of Daniels' paper was a comparison of the hyperopia estimated by the direct ophthalmoscopic examination, which was assumed to be the total hyperopia, with the amount of manifest hyperopia estimated in the ordinary way. In view of my own experience I can only conclude that very inadequate means were taken to get the maximum of manifest hyperopia or that the estimates with the direct ophthalmoscopic examination were quite inaccurate, or that the cases examined were radically different from those we meet in Philadelphia. My own statistics are based on carefully ascertaining the amount of manifest hyperopia by repeated trials under the most favorable conditions, by the use of test-lenses and test-type at the range of four or six metres, taking the strongest convex lens that allowed the best distant vision as the measure of the manifest hyperopia. And taking the correcting lens as chosen under full mydriasis, and confirmed by the shadow-test and the direct ophthalmoscopic examination, as the measure of the total hyperopia.

A word as to the method of obtaining the maximum of manifest hyperopia. My method is to make the test after the approximate amount has been ascertained by the direct ophthalmoscopic examination. The eyes after being allowed a moment's rest have placed before them convex lenses strong enough to certainly over-correct the hyperopia. After finding the extent to which these lenses blur the vision, their strength is gradually reduced by changing them, or placing before them weak concave lenses, until the change no longer improves the vision. Then a card is held first excluding one eye, then the other, to ascertain if both see equally well, and if one eye shows a distinct inferiority to the other the lens before it is still farther reduced until it equals the other in vision, or ceases to be improved by the change. The essential points in such a test are that the lens should over-correct the hyperopia and that all changes should be made without allowing the patient to look without his lenses, and that the two eyes shall be used and tested together. Sometimes I have been able to increase the amount of manifest H. by having the patient read small print through the lenses for a few minutes and then look up at the test card, a trick I learned from my friend Dr. Chas. H. Thomas; and at other times I have gained a very little by placing before the eye an abducting prism, but these are of minor importance.

I am well aware that obtained in this way the manifest H. was distinctly higher, often very much higher, than could be discovered by testing each eye alone, or by commencing with weak convex lenses and increasing their strength gradually until the increase caused a perceptible blurring, and that to a corresponding extent the H. remaining latent was diminished. *But I submit that it is this higher amount that* we ought to regard as the real manifest hyperopia—the highest amount that under ordinary conditions of distant vision the ciliary muscle could be induced to leave to the lenses for correction. It is only what remains after this has been taken from the total that really corresponds to our conception of latent hyperopia.

Again, it is the case that the lens which I took as the measure of the manifest H. was often such only for a brief period, and worn for a few minutes would cause a marked blurring of vision. I had intended illustrating this by one or more cases but I find that Donders in the very process of explaining hyperopia gives such a beautiful illustration of this, that I quote it instead. He *says*:[1] "*In my first investigations* of H. I encountered the difficulty of accurately determining the degree of this anomaly. Thus an eye sometimes at first refused every glass stronger than $\frac{1}{12}$, while it soon afterward gave the preference to $\frac{1}{8}$, and subsequently again chose $\frac{1}{16}$, or $\frac{1}{14}$." In this, which being put as a suppositious case it is fair to take as representative of Donders' experience, there is revealed what Donders according to other passages seems not to have fully appreciated, the extremely variable, inconstant character of the latency of hyperopia.

At one time I fully believed, as it is fair to understand that Donders believed, and as Daniels' statistics clearly indicate, that latency of a portion of the hyperopia was the rule, and its absence the exception, and in childhood and early life the rare exception. The accumulation of the statistics upon which this paper is based have slowly undermined this belief and their tabulation has swept it away altogether. Unless the experience here recorded is entirely exceptional, and it agrees so well with other observed facts that this is improbable, latent hyperopia must be regarded as exceptional among patients as they come to consult us. Whether or not it is more common among these hyperopes who do not so suffer from eye-strain, and therefore are not found among our patients is a matter worthy of careful investigation. But among patients, it is but little if any more frequent, in proportion to the total number of cases than is spasmodic myopia. Is it not rational to suppose that like the latter condition, it is often or largely due to a condition of irritation, or undue irritability rather than a normal tonic state, like that of the sphincters or the vaso-constrictor fibres?

I confess I have never been able to quite accept the idea of a muscular tonic contraction that should be normal in one eye, usual in hyperopic eyes, and quite abnormal and unusual in eyes that have a slightly longer antero-posterior diameter.

Turning now to the matter presented in table I, it is to be noticed that the figures in the first and second column indicating the relative frequency of latent hyperopia are directly opposed to what has been usually held and taught. It is shown that latent hyperopia is least frequent, 21 per cent., before the age of twenty; and most frequent, 47 per cent., between forty-five and fifty, a period at which, according to Daniels, it is almost always absent. It may be well to mention here that although no case of hyperopia latent after the age of fifty occurred during the time covered by these statistics, I have seen a few such cases. One of them was that of a man aged 51 with a total H. of 2.50 D., of which 2. D. was latent. That latency of hyperopia should become less common as the range amplitude of the accommodation diminishes, seems at first glance probable, but a little consideration will show that the reasoning that indicates this is superficial.

Latency of hyperopia depends on the power and activity of the ciliary muscle, and up to middle life these are not diminished. Removal of the punctum proximum depends on increasing rigidity of the lens, the effect of which is to lessen the extreme change of form that the contraction of the ciliary muscle is able to effect in it.

By the figures of the fourth column it is indicated that in those eyes that have latent hyperopia the proportion of the hyperopia thus masked, while varying widely in individual cases (from 5 per cent. to 100 per cent.), is not at all proportioned to the age of the patient, being about equally high before the age of fifteen and after forty-five. While this is true as to the proportion of the hyperopia that is latent, there is, as shown in the last column, some diminution in the amount of latent H. as measured in dioptres; indicating that as age advances, the cases of high hyperopia all become manifest, leaving only the lower degrees that remain partly latent.

Briefly to summarize, the facts to which this paper is designed to direct attention are these:

That the latency of hyperopia is essentially exceptional, inconstant, and abnormal.

That it is not more frequent or proportionately greater in childhood, or in early adult than in middle life.

That the amount of manifest hyperopia discovered depends largely on the method of testing for it.

And from these follow certain practical deductions, viz.:

It would usually be unnecessary to employ a mydriatic to render manifest the total hyperopia, if we only had some certain means of detecting the exceptional cases in which it is necessary.

---

[1] Loc. cit.

A mydriatic is as frequently needed, and as strong a mydriatic is needed to render manifest the total hyperopia at forty-five as at fifteen.

In correcting hyperopia without the use of a mydriatic the assumption should be that the total hyperopia is manifest. To add something for assumed latent hyperopia will, in the majority of cases entail imperfect distant vision, which will continue as long as the lens thus ordered is worn.

In prescribing a lens correcting less than the total hyperopia, in allowing for latency of a part of the hyperopia, we are allowing for an inconstant, temporary, mainly abnormal condition, and should warn the patient of the probable early need for a change of lenses, and that the best and most permanent relief is not to be expected until such change is made.

Discussion.

Dr. Charles Hermon Thomas:—I agree very thoroughly with what Dr. Jackson has said in his paper. I almost regret that he has failed to repeat some things that he has said elsewhere in regard to the allowance for range, *i. e.*, the distance from the test letters at which measurement is made under a mydriatic. I formerly found many cases in which I believed there was latency before the mydriatic was used, or in which there was recurring spasm after the mydriatic, but since I have come to make the allowance of .25 D. for 4 meters in length, or approximately that, I have found very few such cases. In my experience latent hyperopia is scarcely more frequent than pseudo-myopia from spasm. I believe that with allowance made for range as Dr. Jackson has heretofore pointed out, we shall find few cases in which there is after-spasm of the accommodation.

Dr. H. V. Würdemann, Milwaukee:—As a rule I use homatropin in refractive work, and think that these cases of latent hyperopia are about as frequent as the cases occur in which homatropin does not reveal the total error—*i. e.*, about one in twenty. In these cases we are forced to resort to atropin. I usually give the full correction as brought out by homatropin, except in highly hyperopic cases.

Dr. F. C. Hotz, Chicago:—I wish to refer to two points in Dr. Jackson's paper. I was surprised that he found so small a percentage of latent hypermetropia in people up to 30 or 35 years. I was also surprised that the amount did not exceed .75 D. It is true that by letting people wear glasses which correct the manifest hypermetropia, often a part of the hypermetropia that we regard as latent, becomes manifest. But my experience is that wherever we find manifest hypermetropia of a certain degree, and correct that, suspension of accommodation always reveals an additional degree of hypermetropia, showing that there is a certain amount always kept latent in young persons.

In regard to the degree, I am sure that in cases of convergent strabismus, there is certainly always a higher degree of latent hypermetropia than .75 D.

The manifest hypermetropia often shows only 1. D. or 1.5 D., when the total is 3. D. or 4. D. In these two points my experience does not agree with the observations presented in the paper.

Dr. Jas. A. Lydston said: In response to Dr. Jackson's statements to the effect that latent hypermetropia is the exception and not the rule, in our cases of refractive error, it seems to me that we must appreciate fully what that term latent hyperopia implies, and this is to be determined by our particular methods of testing. For example, if we resort to the ophthalmoscope we must fully concur with the doctor when he says "latent hyperopia is the exception and not the rule"—but if we resort to the ordinary methods of testing, without paralysis of the accommodation, then I am convinced by all the cases that have fallen under my observation, and by the experience of all ophthalmologists, that a certain amount of the hyperopia present will be held in abeyance, and constitute the so-called latent hyperopia. Again, when testing our cases and tabulating our statistics it seems that we are prone to forget that the individual may be suffering with a debilitated condition of the system which reacts upon the accommodative mechanism, and thus reveals an error which would otherwise be obscured and thus constitute a latent error, and in this case be styled latent hyperopia. Then too, when the doctor states that the accommodative mechanism is not materially impaired till later life, it appears that his experience does not concur wholly in this respect with that of others. Moyer, basing his statements upon the admirable table of Donders, states that the accommodative power begins to wane as early as 16 years, and is quite noticeably impaired at the age of 30, still more so at 50 years, and is almost obliterated at 75 years. So that this would exercise an influence directly opposite to that claimed by the doctor, in rendering manifest otherwise latent cases of hyperopia.

Dr. B. Alexander Randall, Philadelphia:—There is one small point that is worthy of consideration. As every one is well aware, in standing there is tension of all the muscles concerned in maintaining the upright position, but we do not call that spasm. So in viewing distant objects in hypermetropia, there must always be a certain amount of accommodative effort, which need not be spasmodic but can be relaxed as soon as the need for it passes away. To call every accomodative action of this sort a spasm is a mistake unless it is spasmodically exercised. It is within the control of the individual in part, but is largely an automatic coördinative adjustment.

Dr. Edward Jackson, Philadelphia:—I perhaps did not make prominent enough the influence of different methods of testing. Take for example a case which I saw within a few weeks. There was total hyperopia of 3.5 D. and I could get 3.25 D. of manifest hyperopia. That was by the method which I have used as the basis of this paper. If I tested each eye separately, I could not get full vision with anything over 2. D. convex. The method of testing is essential in unmasking the hyperopia.

I can fully appreciate the surprise of Dr. Hotz, for no one could have been more surprised than I was myself when I found these facts. I fully believed when I commenced this investigation, that the facts would be such as are implied by Donder's remarks, and that up to 20 years of age one half or two-thirds of the hyperopia in almost all cases would be found to be latent. I was surprised to find that in such a large proportion, three-fourths of all patients up to twenty years of age, all the hyperopia could be rendered manifest.

THE FOURTH DEGREE PRISM IN THE CORRECTION OF HYPERPHORIA.

Read in the Section of Ophthalmology at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June 1892.

BY A. E. PRINCE, M.D.,
OF SPRINGFIELD, ILL.

Mr. President and Gentlemen:—My excuse for the presentation of a paper on the fourth degree prism in the correction of hyperphoria, is based on the belief that ophthalmologists as a body are not analyzing these cases with a view to correcting so small an amount of error.

I shall waste none of your valuable time by reference to the differences of opinion which prevail regarding heterophoria in general, but will proceed directly to give the results of my experience with the correction of hyperphoria of low degrees.

It has doubtless been the lot of every member of this Section to meet cases of asthenopia so nearly approximating emmetropia, and having so little apparent disturbance of muscular equilibrium, that it seemed impossible to account for the symptoms, and they have continued to suffer uncorrected.

These cases were made much less frequent by the valuable contribution of Dr. Chisholm on "The Value of the .25 D. cylinder," read before this Section in 1889, at Newport, for previous to that time, astigmatism of smaller degree than .50 D. was relatively seldom corrected.

In still further reducing this class of unrelieved asthenopias, the profession owes its profound thanks to Dr. Stevens, for, whether or not we accept all that he has taught, we must acknowledge that he has given us a nomenclature, instruments and a method of study in muscular dynamics which every student and operator to-day turns to valuable account.

Still a certain number of cases have refused to yield, and have continued to visit persecution upon us by returning again and again, having failed to get relief, whatever prescription may have been made.

Not having a prism in my trial case weaker than one degree, nor an instrument of greater precision than Steven's first phorometer, it was for me, impossible accurately, to measure errors of less than one degree, hence this remained the unit until the publication of the "Maddox Rod Test."

The use of this instrument rendered it apparent that degrees of hyperphoria, varying from one-eighth degree to one-half degree, were many fold more common than all the grosser errors combined, just as an astigmatism of .25 D. is found to exist more frequently than any other degree.

The first practical result, so far as my practice was concerned, occurred in the following case:

Miss L. B., æt. 21, had previously been under my observation during two periods of several weeks each, and had suffered with the following symptoms:

For about five years has seldom passed a day without an aching in and back of the eyes. About 2 P.M. a tired feeling would commence, and grow worse during the remainder of the day. There would often be a neuralgic pain in the right side of the head, which would persist until relieved by sleep. She could not read for five minutes with freedom from discomfort.

An analysis of her refraction revealed less than .25 D. of either spherical or cylindrical error. On one occasion I prescribed plus .50 S., and on another, an orthoscopic combination of Brudenel Carter, consisting of plus 1.25 S. with three degrees prism, base inward, which I formerly used a great deal. This latter glass relieving proportionately both recti and ciliary muscles, gave her considerable comfort, and enabled her to do a moderate amount of work, but even this, after a time, was no longer helpful, and her asthenopia and suffering from headache increased.

Again I tested her adduction, abduction, and right and left sursumduction, but discovered nothing. Again I went over her refraction under complete mydriasis with the same result. Upon the application of the rod test, it was observed that she had so slight a degree of hyperphoria that it was reversed by a prism of one degree. As this error seemed to be constant, I ordered a prism of one-half degree which was subsequently replaced by two of one-fourth degree each, base downward before the left eye, and upward before the right.

The first evening after commencing to use the glass she could read without discomfort, and has continued free from headache or discomfort from that day to this.

Some months since, in talking with one of the prominent advocates of graduated tenotomy, I was assured that the probabilities were large that a much greater degree of hyperphoria would be found to exist if the patient were retested after this length of time. Accordingly the patient was summoned, and an examination made to ascertain, if possible, whether or not the relief came from partial correction of a much larger error. Upon this examination, to which I brought the aid of the Steven's improved phorometer, I found an apparent one degree, which increase I had her wear for twenty-four hours, but the original prescription was preferred.

After witnessing the benefit derived from the fourth degree prism in this case, I ordered trial prisms of half and quarter degrees, and thereafter submitted all doubtful cases to analysis, relative to ascertaining the presence of the smallest amount of hyperphoria detected by the rod test. While a quarter to a half degree was found in a large proportion of eyes, and often one, two and sometimes three degrees were observed with no asthenopia, or other reflex symptoms, still a sufficiently large number of cases were met in which the various local and reflex disturbances were traceable to, and relieved by the fourth degree correction, that I felt encouraged in pursuing the inquiry, and now regard no examination complete which is conducted with less precision.

I have not prepared a statistical collection of facts, and results of the multitude of tests made for adduction, abduction and right and left sursumduction, remote and in accommodation, but have chosen, to serve my purpose, brief extracts of a dozen cases selected to illustrate some of the various phases of discomfort, in which relief has been found to result from the use of the fourth degree prism, in most of which all previous remedies had failed.

Case 2.—Illustrating emmetropia with one-fourth degree left hyperphoria. Miss Mary L. æt. 24, commenced eight years ago to complain of photophobia and incapacity to use the eyes at night. One of the early symptoms was a tendency to squint the eyes, and scowl in reading. She never experienced very much pain in the eyes and only occasionally suffered from headaches, and then not very much. Both in reading and writing, the letters would seem to dance, and the lines would seem to wave. This latter symptom was relieved by a colored glass, which was worn for a year, after which study was more or less discontinued, and the colored glass was worn occasionally. Five years ago I was consulted and failed to find any error whatever, but gave her a plus .50 D. S. with the hope that the diminished strain on her accommodation might give the eyes some comfort. These glasses were worn for reading only, and helped some, but, notwithstanding, the main symptoms have continued, and she has never been able to read at night, or do any work continously without discomfort. After attempting to use the eyes a burning sensation is experienced the following morning. After looking at anything intently for a short time the eyes feel as though they had been wrenched, the left eye particularly.

She consulted me again on March 29, 1892, but repeated examination failed to discover any refraction error.

One-half degree of left hyperphoria was discovered, and a prism given for its correction. This was worn in the trial frames for two hours with perfect ease, and she expressed a feeling of rest which had not been experienced either with or without glasses for several years. One-fourth degree in permanent frames was ordered before each eye, and she was requested to report in a month.

Before that time she returned, saying that the permanent glass had not been so restful as the trial glass had seemed to be, and on examination it was found that the hyperphoria was scarcely one-half degree, hence slightly over-corrected. One fourth degree was put in trial frames, and she was induced to remain a few days, during which perfect comfort was experienced. The correction was made permanent, and was found after one month to be satisfactory.

This case is one of several in which the discomfort was relieved by a fourth degree prism to one eye only.

Case 3.—Illustrating plus .50 C. 90° one-fourth degree right hyperphoria.

Miss Ida S., æt. 19, consulted me from Lincoln, Ill., where she was attending school. She complained as follows:

For several years she had been obliged to save her eyes, and experienced photophobia and pain on using them. She was unable to study more than twenty minutes, and was afraid she would be obliged to give up her school. A burning and smarting of the lids was experienced on application for even a brief period of time.

Upon examination, under complete mydriasis, plus .50 C., axis 90 degrees was found and prescribed. Upon first examination no heterophoria was discovered. The glasses were comfortable, yet she could not endure continuous work. After three months of rest she was no better. A second time she consulted me, and upon examination I found one-fourth degree of left hyperphoria. It was also found that she was quite sensitive to the reversal of the prism. It was ordered in a light trial frame, to be worn over her cylindrical correction long enough to demonstrate its efficiency.

After two weeks she reported that the strain seemed relieved, and she could do a large amount of work while wearing the trial glass, but when it was left off, she could use the eyes but a few minutes.

Case 4.—Illnstrating recurrent conjunctival hyperæmia.

Miss Maude T., Springfield, Ill., æt. 18. While in school in the winter of 1883, the eyes became inflamed and red, and her family physician prescribed for her. The eyes were bandaged, and she was confined in a dark room for about four days. Improvement followed, and she was able to resume her school work for the remainder of the year, but the eyes did not become quite comfortable. During the following vacation the eyes were not in use for the purposes of studying, but still there was no time when she became quite unconscious of having eyes. From this time until the winter of 1887 she had no especial difficulty.

In the winter of 1887 she began to suffer from weakness and was taken out of school, and did not resume her studies for the rest of the year. In 1888 she had no especial difficulty, and finished her school year.

In 1889 she began to have trouble in March, and was treated by her family physician for granulated lids, which recovered in a large measure in the course of a few months, but school was not resumed until the following fall.

During the winter of 1890-91 she did some studying at home, and experienced no trouble with the eyes; was fairly comfortable up to February, 1892. At this time the eyes broke down, and she again consulted her family physician, by whom she was treated for inflammation until March 1.

In all of these attacks the trouble with the eyes was preceded by headaches which "seemed to extend to the eyes."

On consulting me she complained of burning of the eyes, and a feeling as though the eyes had been wrenched. Pain back in the sockets was experienced on extreme lateral movement.

Examination revealed an astigmatism of .25 D. and hyperphoria one-half degree. The astigmatism was ignored for a time, and trial frames were worn for a week continuously with one-fourth degree prism, base upward, before the left eye, and downward before the right. Absolute comfort was experienced, and a glass was ordered in which the cylindrical error was incorporated.

At the end of a week all inflammation and soreness in the muscles had disappeared, and she could resume her studies with comfort.

A permanent glass was given, and she reported a month later, "Eyes absolutely restful."

Case 5.—Illustrating rapid nictitation. Kirk O., Petersburg, Ill., æt. 11. Called on me April 1, 1892, with a history for the past six months of holding his book very close to his eyes when reading, and of squinting at the same time so as to secure a very narrow palpebral aperture. In the evening he was subject to very rapid winking whenever looking at books or pictures, and would have periods of rubbing the eyes. Examined under homatropine, it was found that he was emmetropic. One-half degree of left hyperphoria was discovered, and a prism of one-fourth degree, base downward, before the left eye, base upward before the right, was prescribed and worn for five weeks, when I saw him for the second time. All symptoms of winking and squinting had disappeared. Since wearing the glasses the book is held at the usual range.

Case 6.—Illustrating asthenopia with astigmatism; hyperphoria one degree, and esophoria nine degrees.

(One of the most interesting cases is the following, on account of the combination with anisometropic-astigmatism and esophoria.)

Louis H. M., editor, æt. 32, asthenopic symptoms commenced about seven years ago, and he especially noticed a sensation which is described by the patient as "pulsation of the blood vessels of the lower lid," for which he sought relief in St. Louis. Glasses were prescribed to correct an error of refraction; not deriving comfort, he returned at intervals varying from one to two months, for nearly two years, during which the right glass was changed several times. He then sought relief in Chicago, where he made five trips extending over a period of four years, and at each visit received a different pair of glasses, and on the last, an additional glass for reading. No permanent comfort was obtained, and he was obliged to discontinue his editorial work, and almost all outside reading. Reading by artificial light was out of the question.

In November, 1891, he suffered from two superficial ulcers of the cornea, which yielded to treatment. A month later I was consulted for the first time, and found right eye minus 1.50 S., minus .75 C., axis 180°, left eye plus .25 S. minus .75 C., axis 180°; esophoria 6 degrees, hyperphoria 1 degree.

The sphero-cylinder was ordered, and the heterophoria ignored until April 4, 1892. During this period he had been able to use the eyes to a somewhat greater extent, but had never experienced a day of absolute comfort. On April 4, hyperphoria, one degree and esophoria nine degrees were found. In order to discriminate from which correction the greater relief was obtained, the esophoria was ignored, and half of the hyperphoria was corrected by one-half degree prism, base downward, before the left eye. On April 5 he reports that he does not remember a day in two years so nearly approximating absolute comfort.

April 6.—The remainder of the hyperphoria was corrected by a one-half degree prism before the right eye.

April 7.—Not so comfortable.

April 8.—Still not so comfortable; return to one-fourth degree in each eye, which, after a week of comfort, was incorporated with his sphero-cylinder.

He was told that he still had a high degree of esophoria, and might require a tenotomy or prism.

June 6.—Says, "I suffer from absolutely no discomfort; can now read ten or twelve columns of fine newspaper print, without realizing that I have used my eyes."

This case illustrates the relative effect and the importance of detection and correction of a small amount of hyperphoria, as compared with a large degree of esophoria.

Case 7.—Illustrating neurasthenia. Miss Nellie A., æt. 20, teacher.

Consulted me in January, 1891, with the following history. At about ten years of age she remembers being troubled with blurring, and was obliged to remain out of school a portion of the school year. She cannot remember when the light did not hurt her eyes.

At twelve years of age she found some relief from colored glasses, which were worn to and from school. From this time she had a feeling of weight pressing down, seemingly over the eyes, so that a great effort was required to look up. Together with this, she suffered from general physical exhaustion, and had a feeling as though she was straining every nerve in the effort to fix the gaze on objects. This was worse when fatigued, and particularly experienced in the afternoon of every day, and by night she was usually sick with headache.

In the morning after a good night's sleep she would feel comfortable for a variable time, depending on the use of her eyes. With increased application trouble would begin about the middle of the forenoon. She always felt better on cloudy days.

When looking at an object for some time, the eyes would assume a feeling as though they were fixed in a staring gaze, which feeling would continue though the eyes were directed towards various objects, and it was only an effort of the will that this unnatural feeling could be shaken off.

After reading, she would become very nervous, so that she could not write on account of trembling. In this condition she could not read two minutes.

She was often troubled with "twitching of the eyes." The muscles around the eye would jerk in a very amazing manner. A prominent symptom was that of dryness, provoking an inclination to rub the margins of the lids.

I found by an examination under mydriasis, emmetropia, right hyperphoria one-half degree, to the correction of which she was very sensitive. Prescribed R. E. one-fourth degree base downward, L. E. one-fourth degree, base upward.

The following letter was received after one week:

"I am very much pleased with my glasses; it will be no cross for me to wear them all the time, for they are so restful; I cannot bear to take them off. Those headaches have not troubled me, and I have not been so nervous. Everything looks very plain, and it is such a relief not to have to strain every nerve to see any object."

It is five months since commencing the use of the glasses, and she now tells me that she has not had a single headache except on one occasion when she broke the glass, and was without them four days.

The first day she noticed that she was much more tired than usual, but did not suffer from pain. On the second day, and until she received the glasses again, she suffered in the old manner, and to a similar degree.

While wearing the glasses there is no photophobia, but leaving them off will provoke photophobia and fatigue in from one to two hours. She regards the relief from the glasses as absolute.

Case 8.—Illustrating drowsiness. Mrs. C. F. D., æt. 29, Ashland, Ill.

She commenced having trouble five years ago, for which glasses were prescribed. They were worn three years, more or less.

During the last year and a half, they have not relieved her condition. She now consults me again on account of pain over both eyes, extending into the temples. This pain is aggravated by looking down. Discomfort increases as the day advances, and is proportionate to the use of her eyes.

Occasionally the eyes burn, lasting for short periods of five to ten minutes. Complains of drowsiness coming on during the day at irregular intervals.

These spells are sometimes of short duration, but may continue all day. Almost invariably gets sleepy immediately after supper, and drops off to sleep unless compelled to remain up. Examination reveals one-half degree of left hyperphoria.

Independent of eye pain, has pain in back and back of head; cold feet and hands.

℞. R. E. one-fourth degree, base up.
L. E. one-fourth degree, base down.

Relief was prompt, and she reported after one month that she could open her eyes wide, with no tendency to frown, and that the symptoms of drowsiness had disappeared.

Case 9.—Illustrating epiphora. Miss Lizzie L., æt. 14. Presented herself for examination Jan. 30, 1892. She complained that for about two years she has been troubled with excessive lachrymation, and almost constant burning of the eyes. Objects seemed to blur at times, but she has never been troubled with seeing double. She has suffered from frontal headaches for several years, which have recently been very bad. Upon examination it was found that she was emmetropic, and that she had left hyperphoria one-half degree and esophoria three degrees. She was especially sensitive to the prism which corrected her hyperphoria, and I concluded to ignore the esophoria and correct the hyperphoria by a prism one-fourth degree before each eye. She reports as follows, March 7, 1892: "I promised to let you know how my eyes were after wearing my glasses one month. I could not do without them now, they have done me so much good. I never have the headache as I used to, and I can read or sew all day without having to rest my eyes. I very seldom have to wipe them, and before, it was every five minutes."

Case 10.—Illustrating recurrent migraine of severe type. Mrs. T. S., Decatur, Ill.

Following measles five years ago, she complained of terrible headaches, associated with confusion of sight, which she called "blind headache." These headaches would yield to no treatment, but after several hours, she would drop to sleep and awaken refreshed. During the intervals which were from a week to ten days, she would not suffer from eye symptoms, and could do any kind of fancy work.

Having exhausted the patience and skill of her family physician, she was recommended to consult an oculist and ascertain if any possible trouble could be found in the eyes to account for the recurrence of the headaches. This was in November, 1891. It was found that she had minus .75 C. axis 0.°, each eye, and one degree of right hyperphoria. Two prescriptions were made in order to ascertain which would be preferred; one of one-fourth degree each eye, and the other of one-half degree on cylinder of minus .75 C., axis 180 degrees. She reported that while the weaker glass was worn with comfort, she could not wear the stronger. She reported to me again June 4, 1892: "Since wearing my glasses, now eight months, I have never had a bad headache, and could not be induced to go without them."

Case 11 illustrates one of the worst types of migraine without eye symptom, but relieved by correction of hyperphoria and astigmatism. Joseph K., æt. 38, jeweler. For fifteen years has suffered with violent attacks of hemicrania, averaging once a week. There are no symptoms of eye strain. Reading does not provoke attacks, but they are precipitated by travel and sports. A day in St. Louis or Chicago, or fishing or hunting, is followed by an attack. These attacks last from sixteen to thirty-two hours, and during the severity the patient can neither sit nor lie, but must rest in a reclining position with eyes closed.

His family physician suggested an examination of the eyes, with the following result: R. E. plus .50 S. plus 50 C. 90°, ¼° hyperphoria; L. E. plus .50 S. plus .25 C. 90, ¼° cataphoria.

He was more sensitive to the hyperphoria than to the sphero-cylinder, and a glass was made correcting these elements.

He has worn the glass sixteen months with but six attacks, but one of which was as severe as those from which he formerly suffered.

Case 12.—Illustrating burning of the lids and headache. Miss Minnie B., Greenview, Ill., consulted me January 1, 1892, regarding a headache which originated in Germany three years ago, and which had persisted ever since, and resisted the action of medicine on numerous occasions when she sought treatment. Headache was mostly frontal, and accompanied by a burning sensation of the upper lids, and a tendency for the eyes to close. She would frequently have difficulty in opening the eyes and looking directly at objects, although she did not complain of diplopia.

The pain was at times worse in the morning, and at other times worse in the evening; nothing constant. Upon examination of her refraction, it was found that she had R. E. plus .25 C. 90 degrees, and L. E. minus .25 D. S. Right hyperphoria one-half degree, and esophoria four degrees. The prescription was made of one-fourth degree, base upward in the right eye, and downward in the left, upon which her correction was ground; esophoria ignored.

January 25. She reports to-day that she is greatly relieved; she has no more burning of the upper lids, and no more of the tendency of the eyes to close, and her headaches are greatly ameliorated. There is a slight discomfort at times which is scarcely worth mentioning.

The following matters of detail are urged, to secure the greatest possible degree of precision:

1. Secure a perfect Maddox rod test, which is thought to be superior to Stevens for these delicate measurements: first, because the images on the retina are entirely dissimilar and have no tendency to blend; second, from the fact that they can be superimposed, thus facilitating comparison, which is especially important in the detection of small degrees of error; third, because comparison is more readily made between the hyperphoria and equivalent corresponding cataphoria, thus eliminating errors of observation or statement.

From the fact that these rods are drawn, a certain portion of them are defective, being slightly conical, which can be detected by inverting the rod before the normal eye.

To increase the efficiency of the method, at my suggestion, F. A. Hardy & Co. have in process of manufacture a phorometer, the essential portion of which consists of two 2° prisms, which rotate in opposite directions over one another so as to present before the rod every fraction of a degree from 0, where they are neutralized, to six degrees, when they act together. An arc is graduated to one-eighth degree, so that the refraction can be accurately read off, as well as the nature of the error, whether it be esophoria, exophoria, or right or left hyperphoria.

2. Make the point of observation the smallest compatible gas jet. By doing this a narrower light streak is observed, which, when the rod is in the vertical position before the eye, should, in the absence of hyperphoria, exactly cut the flame.

3. Place the gas jet or taper before a dark background, which will increase the capacity of the patient to detect a small error. On several occasions hyperphoria has been overlooked, and other errors which were present corrected, later to find upon more careful observation with a reduced light and dark background, that one or two quarters were present, the correction of which gave complete relief.

4. Compare the hyperphoria with the corresponding cataphoria, to which it should be equivalent. In event of discrepancy in these cases, it has been found the best practice to correct the smallest degree in the trial frames, and test again to ascertain if more becomes manifest.

5. Following the suggestion of others, it is believed that a much larger percentage of satisfaction can be secured by being provided with a variety of light steel frames, with bridges of various heights and prominence, supplied with long screws to facilitate

changing of prisms, which should be worn for a time, either with or without such other correction as may be present, in order to ascertain whether the prism in question is acceptable to the patient. Each case is a law unto itself.

Some cases will be found in which the heterophoria is provisionally corrected with comfort to the patient, by the muscular adjustment, while in others an error of one-fourth degree will require a corresponding prism before relief will be obtained. In some cases the weight of the trial frame usually employed, is so great as to vitiate an observation, and lead the patient to pass judgment against the prism, which, had the light, well fitting frame been employed, would have been reversed.[1]

A word may not be amiss concerning the measurement of the weak prism, whereby the physician may be assured that his prescription had been filled by the optician. There are various methods known to the mathematical optician which are impracticable in the practice of the physician, who must, more than likely, rely on the method of neutralization. To this end, as well as in the original detection of the error, I have found the Maddox rod to serve best. Knowing the prismatic error possessed by one's self, and having corrected it, the rod causes the ray of light to appear to cut the flame seen by the fellow eye. The glass in question is now held before the eyes, when an appreciable vertical displacement will occur. The neutralizing glass is now placed before the glass to be tested when the equilibrium will be restored. This method is simple and can be operated by anyone having good binocular vision, and an approximation to orthophoria.

Dr. H. Gradle, Chicago:—The significance of any results diminish as they approach in numerical value the errors incident to the method employed. In criticising the results obtained with one-fourth degree prisms, I would only say that the least possible tilting of the spectacle frame from the vertical position will produce a difference greater than that mentioned. Most of us can recall occasional instances where patients were satisfied with certain weak glasses which on subsequent tests proved to be incorrect and sometimes almost the reverse of what was ordered, and still the patient was suited.

Dr. Samuel D. Risley, Philadelphia:—I should like to call attention to one error occasionally made in the construction of spectacles, although not a very frequent one. The optician will sometimes grind a compound lens upon a glass whose surfaces are not exactly parallel, so that the sphero-cylindrical lens will also be prismatic. I remember one case in which almost a 2° prism was thus produced by the carelessness of the optician.

Dr. Prince closing:—In answer to the hypothetical objection that many glasses are worn with comfort which from fault of lenses or frames are decentered so as to effect a prismatic action greater than ½°, it is sufficient to say that a great number of cases occur who are unable to work with freedom from strain after a spherical correction has been made, who are rendered comfortable by slightly decentering the lenses by readjusting the frames. The fact that the great majority of persons can wear badly fitting glasses does not militate against the claim that a few demand the absolute centering in the vertical meridian.

FACIAL EXPRESSIONS AS INFLUENCED BY THE OCULAR MUSCLES.

Read in the Section of Ophthalmology at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY GEORGE T. STEVENS, M.D.,
OF NEW YORK.

In the course of some years of close observation of the anomalies of the muscles which govern the movements of the eyes, the fact that remarkable changes often follow the modification of these muscles led me not only to regard with greater care these facial changes, but to bring to the subject the aid of photography. Photographic portraits of more than two thousand persons have been taken, the records of whose ocular-muscle conditions have been carefully and repeatedly made.

We have thus for the first time a series of observations in which the facial expressions are registered by photography while pains-taking determinations of the ocular-muscle conditions are faithfully recorded. The result of the study has been to demonstrate that certain well defined types of facial expression are not only associated with but are dependent upon certain relative tensions of the oculo-motor muscles. With the state of equilibrium of the eye muscles, orthophoria, the expression is one of greater repose that with any of the states of heterophoria. The eye brows form each a moderate and regular curve, marking the border of the orbit, the lower border of the brow corresponding to the orbital border.

The inner extremity descends towards the nose, but does not turn downward into the depression bounded by the nose and orbit. There is no sharp turn or curve at either extremity. The mouth is nearly horizontal or curving very slightly upwards at the centre. The lips in repose are firm but not compressed, and the upper one is well proportioned. The chin is rounded, neither square nor pointedly oval. The lines of the forehead are not especially conspicuous. The facial lines are moderately spreading.

With esophoria the brows are compressed, the extremities often curve suddenly downwards, the inner extremity sinking into the depression bounded by the nose and orbital border. The palpebral fissure is usually less widely open than in orthophoria or exophoria. The lips are firm, the upper one short. The posterior portion of the alæ of the nose drawn slightly upward, the superficial lines or grooves upward from nose erect and distinct; especially in middle life and later; transverse lines upon the forehead low; the naso-labial and cantho-malar grooves spreading. The lower part of the face is broad.

With exophoria the brows are usually raised, often strongly arched; palpebral fissure often wide; upper lid rather conspicuous; upper lip long; corners of the mouth often drawn up and the mouth curving down at the centre; lower part of the face usually narrow; principal grooves of the face more vertical than with esophoria. The transverse lines on the forehead are mostly above the centre. Hyperphoria is characterized by irregular features. On the side, the visual line of which tends to rise above the other, the brow is depressed, while the brow of the side whose visual line tends downward is elevated. Thus the brow and neighboring tissues of one side aid in depressing the front of the eye, while, on the other hand, by the elevation of the opposite brow less demand is made upon the muscle which rotates that eye upward. These contrary actions demanded by the relations of the visual lines in hyperphoria affect the whole face resulting in a want of harmony of the two sides. The angle of the mouth, on the side on which the brow is depressed, is drawn upward, while the other angle is depressed. Thus one side of the face appears longer than the other.

---

[1] Sets of a dozen frames with assorted bridges, and a series of prisms to fit, are furnished by F. A. Hardy & Co.

There are a number of sub-types depending on hyperesophoria and hyperexophoria. While there are apparent exceptions to these rules, as to most rules, and while the bony structure must give to the face its general form, the law is very generally prevalent.

The recognition of these types of expression is useful to the oculist as well as to the artist. Any one of the types may be modified or transformed to another type by modifications of the relative tensions of the muscles which rotate the eyes.

THE TREATMENT OF INCIPIENT CATARACT.

Read in the Section of Ophthalmology, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY A. J. ERWIN, M.D.,
OF MANSFIELD, OHIO.

The surgery mania is so prevalent in our profession that the suggestion of other therapeutic agents is not always tolerated; especially is this true of cataract. In fact, the modern therapeutics of cataract is excessively surgical. Noyes admits that cataract has been cured by medicinal agents, but it seems to him so questionable that he has not even formulated a treatment for it. While Edward Meyer "believes that the recorded cases of recovery from cataract by medication may be attributed to error of diagnosis." (Sic.) Such being the teaching of modern authors, it is not probable that many oculists have undertaken a persistent systematic treatment of incipient cataract. No one, I apprehend, will deny my contention that an incipient cataract, while the eye has an acuity of vision equal to the average aphakous eye should be stopped, if possible, even though there should not be any improvement of sight, but it is not necessary to argue this point before an audience of specialists, you all understand it; I shall, therefore, not delay in bringing before you the point at issue, viz., can the progress of incipient cataract be arrested? In answer to this question, I beg to present to you the history of a few cases of incipient cataract taken from the records of my own clinic, viz.:

Case 1.—Mrs. J. R. Richardson, æt. 50, Mansfield, Ohio. February 11, 1886. Incipient cataract, O. D. V=20-100. O. S. V.=20-100. Treatment, galvanism and tincture of iodine about the eyes three times per week, with iron tonics daily. When discharged after two months treatment examination showed O. D. V=20-40, O. S. V=20-40, which continues the same to this date (August 18, 1892).

Case 2.—John Hull, æt. 82; Mansfield, Ohio. June 12, 1886. Incipient cataract, O. D. V=20-200. O. S. V=20-100. Treatment galvanism and tincture of iodine about the eyes, three to six times per week, with elix. calisaya, iron and strychnia three times daily. When discharged after five weeks' treatment, he had O. D. V.=20-100, O. S. V.=20-50, which was maintained until about Jan. 1, 1889. He returned for treatment Aug. 31, 1889, with O. D. V.=light perception, O. S. V. =12-100. His former treatment was exactly repeated for six weeks; when discharged he had O. D. V.= not improved, A. S. V. =12-50, which continued as at date of discharge until his death, two and a half years later.

Case 3.—Mrs. E. Chandler, æt. 65; Mansfield, Ohio, Oct. 9. 1888. Incipient cataract O. D. V.= fingers one foot, O. S. V.= 20-60. Treatment externally, galvanism and tincture of iodine daily, citrate of iron, quinine, pepsin and bismuth with each meal. When discharged after two months' treatment she had O. D. same, O. S. V.=20-40. *Six months* later O. D. matured, but to this date O. S. maintains vision 20-40.

Case 4.—Israel Swineford, æt. 70, Pavonia, Ohio. May 4, 1889. Incipient cataract, O. D. V.=10-100, O. S. V.=5-200. Did not take treatment until July 23, 1889, at which time he had A. D. V.=5-100, O. S. V.=2-200, Treatment, elix. calisaya, iron and strychnine, with each meal, one drachm. With galvanism and tincture of iodine about the eyes three times per week. Dismissed after six weeks' treatment with vision O. D.=13-100, O. S.=2-200. July 4, 1891, no change. I have not seen Mr. Swineford since. (He had the grip a year since, and has now O. D. V.=3-100, O. S. V.=2-200, August, 1892.)

Case 5.—Mrs. John Hull, æt. 80; Mansfield, Ohio, Aug. 31, 1889. Incipient cataract O. D. V.=12-100, O. S.= 2-100. Treatment, galvanism and tincture of iodine about the eyes, with iron and quinine tonics with each meal. The applications were made from three to six times per week from Aug. 31 to Oct. 31, by which time O. D. had improved to 12-50, O. S. remaining at 2-100. There has not been any change in the acuity of her vision since.

Case 6.—Mrs. Jacob Schall, æt. 65, Mansfield, Ohio, Oct. 17, 1889. Incipient cataract O. D. V.=20-40, O. S. V.=20-40. Treatment, galvanism and tincture of iodine, with elix. calisaya, iron and strychnine. Dismissed Nov. 25 with O. D. V. =20-30, O. S. V.=20-30. No change in the amount of vision to this date.

Case 7.—Mrs. F. E. Cope, æt. 70. Mansfield, Ohio, Nov. 25, 1889. Incipient cataract and retinitis albuminurica, with general dropsy. O. D. V.=20-100. O. S.=15-100. Treatment, tincture Ferri chlor. and quinine, and later galvanism and tincture iodine over eye lids. Dismissed Jan. 14, 1890, with visual acuity O. D.= 20-50, O. S.=20-70. Albumen and dropsy had entirely disappeared. No increase of of cataract to this date.

Case 8.—Mrs. Henderson Richey, æt. 75, Mansfield, Ohio, Dec. 26, 1889. Incipient cataract O. D.=4-200, O. S. V.= 20-100. Treatment, galvanism and tinct. of iodine over eyelids, with elix. colisaya, iron and strych., daily. Dismissed Feb. 25, 1890, with vision O. D.=6-200, O. S. 20-50.

July 1, 1890, O. D. fingers at one foot, O. S.=20-40. July 1, 1891, I extracted R.= cateract at her demand against my judgment, O. S. being so good. Sept. 15, 1891 O. D. V.= 20-30 O. S. V.=20-40. Corrected, but unable to wear cataract glass on account of the confusion it caused as usual. O. S. cataract has not made any advance since.

Case 9.—Catharine Orwiler, æt. 68, New Washington, O., April 19, 1890. Incipient cataract, O. D. V.=20-50. O. S. V.= 10-100. Treatment, galvanism and tinct. iodine over eyelids daily, and citrate of iron and quinine. Discharged June 21, 1890. Vision O. D.=20-30, O. S.= 20-100. I have not seen this woman since, but I am informed that her sight is still about as good as when discharged.

Case 10.—Mrs. Susan Law, æt. 80, Mansfield, O. May 2, 1890. Incipient cataract, O. D. V.= 10-100, O. S. V.= 1-200. Treatment, elix. calisaya, iron and strych., with the usual application of galvanism and tinct. iodine. Discharged May 24, 1890, with vision O. D. 20-100, O. S. not improved.

July 9, 1891, O. D. V.= 20-100. O. S. cataract mature V= perception of light.

Case 11.—Mrs. S. B. Markel, æt. 50, Ashland, O., Nov. 18, 1890. O. D. posterior capsular cataract with fluid vitreous, vision =light perception. O. S. incipient lenticular cataract, vision= 20-70. Treatment daily for five weeks with the galvanism and tincture of iodine and iron tonics. Vision at discharge and to this date O. D. not improved, O. S. 20-40.

Case 12.—John Bergderfer, æt. 67, Catawba Island, O., Dec. 15, 1890. O. D. hypermature cataract with fluid vitreous and perception of light. O. S. V.= 20-100. Incipient cataract following six months after a stroke on the eye. Treatment citrate of iron and quinine with pepsin and bismuth, and the usual application daily of galvanism and tincture of iodine. Discharged after five weeks treatment with vision O. S. 20-100. No relapse to this date.

During the past year I have treated four other cases of incipient cataract in the same way, with about the same results, but they are not described in detail because of the recent date of their treatment. My experience convinces me that in nearly every case of incipient cataract we can save to our patients for a few years at least, their existing amount of vision, which in many cases may be even more serviceable than that of an aphakous eye.

CAMPHOR.—Dr. Karl Rosaer, in *Zeitschrift f. Therapie*, recommends liquid parafine as a solvent for camphor for subcutaneous injection; on warming, a clear solution is obtained which will keep a long time.

THE NEGLECT OF MEDICAL EDUCATION IN THE UNIVERSITIES.

BY BAYARD HOLMES, B.S., M.D.,
PROFESSOR OF SURGICAL PATHOLOGY AND BACTERIOLOGY IN THE COLLEGE OF PHYSICIANS AND SURGEONS.

It is now the fashion for every medical college to have a "University connection." This is a condition, often, as we have reason to know, of the most distant and unstable character. In some cases it means that the medical school is advertised in the announcement of the university and helps to swell the number of university matriculates, but that it is autocratic and independent of the university in all its acts and the university is free from all financial responsibilty in the medical school. In other cases it means that the university is responsible for the housing of the medical department which it has farmed out to a few physicians. These men conduct the affairs of the institution as they see fit and, we regret to say, without regard to the interests of any but themselves. Some of these university medical schools still have seven or eight professors as they did fifteen years ago. The increase in medical lore and the improvement in methods of medical investigation have made no additions to their curriculum or to their faculty.

But it is not of the private universities that the profession has a right to complain. Under our existing laws and customs, what they have is theirs to do with as they please. With the State Universities it is different. They are the proper subjects of criticism. They have entered the field of medical education to teach and not to bolster up the acquaintance and reputation of any set of men. The State medical schools should then require of their students the very best preliminary education, the most extensive course of study, and the most rigid examination and clinical demonstration of fitness for graduation. It is notorious that the State University medical schools in order to encourage scholarship (?) ask no tuition fees, and yet it is equally notorious that students are not excluded from these schools for illiteracy. Therefore the "medics" in the large State universities are the most uncultured and uninfluential of the lot of students. Medicine is disgraced by the boisterous crowd, and anything like adequate teaching of such students is impossible. The course of study in those schools is not more extensive than in the best private schools. In no sense do they lead in education. Their degrading effect on medical education would be greater but for the fact that most of them are situated in small cities, and therefore they are rarely rivals of metropolitan schools.

The position of the medical department in the American university is unique. Medicine is the natural recipient of a large portion of the men who take the bachelors' degree in science. Medicine should have a larger portion of the Bachelors of Science than the law has of the Bachelors of Arts. *In looking* over the class statistics in the college magazines that lay on our table, we find that between thirty and forty per cent. of the June graduates are put down as prospective lawyers; the balance of eighty per cent. as prospective preachers; while only five per cent. are reckoned as prospective doctors. In the Law departments of our universities over half the matriculates are graduates in the arts, while the most fortuitously situated medical schools can not boast of more than ten or fifteen per cent. of students who have the bachelors' degree.

Of all the occupations of life, medicine is the most benevolent. In this respect it should be a rival of the ministry. It is the one occupation in which there is a life long pursuit of science. In this respect it should compete with the mechanical arts and engineering. It is the one occupation in which a man is free from the crushing influences of our modern growth of monopolies, and it is the only profession in which a man may expect to earn a living from the beginning. In these respects it has no rival. It is astonishing then that medicine receives so small a proportion of our college educated men.

We cannot attribute this neglect of medicine to its comparatively small financial rewards, because these rewards come soon and last to the end of the doctor's life. We cannot attribute it to the hard work and long hours, because the other professions are hardly less exacting. It cannot be because a larger proportion of men love the study of the humanities and literature and a smaller number the sciences, because the former are notably artificial. But we believe the cause is to be sought in the general neglect of the sciences by the universities, and the special neglect of that fruition of the sciences, medical science. The professors in the most celebrated, and we believe the most overrated university medical school in the country, not only receive a smaller salary than any other professors in that renowned faculty, but less than many of its tutors. Again, the professorships in this institution seem to be under a protective entail limiting appointments to certain families. In other branches of the same university no such systematic favoritism is manifested. This medical school, though most fortuitously situated, and though holding a very high, if not the highest, place in the esteem of the profession, does not attract any considerable percentage from the enormous classes that yearly graduate from the arts and science departments of the same university. That is to say, this great medical school is not looked upon with favor by students of the university. The scientific spirit does not so pervade the institution that the rapidly increasing students are attracted to medicine as a field of mental activity.

Undergraduates are led to the selection of post-graduate fields of study by fashion, by the influence of the undergraduate professors, and by distinction already attained by former aspirants. If there is no place in a medical school open to ability, original research and honest and successful work, the ambitious and high-minded student will select a department in which birth and marriage play a smaller part in the bestowal of professorships and honors.

To the profession at large, this strange condition of affairs in so many of our medical colleges is not more ridiculous than it is exasperating.

Again, the too "practical" character of medical teaching drives away real students and scholars. While in other branches of the university a constant effort is made by means of lectures, theses and honors, to increase that indefinite educational element which has been termed culture, these efforts are not apparent in the medical school. The medical school seems to be given over to the sordid clinician and the chemist, to the humdrum lecturer and the ranting specialists. Real culture is the quality which our medical schools most need.

The students in this department are in most institutions under different rules and regulations, both in regard to requirements and honors, from students even in the other professional schools.

It is unfortunate that we have so many medical schools, but more unfortunate that we have only one sort. The requirements of the oldest and we believe richest medical school in the United States now barely comes within the minimum requirements of the State Board of Health of Illinois, and not within the minimum of the Association of American Medical Colleges. The fees of this school also are as low as those of a provincial college.

The medical profession has abundant reason to complain of the stingy manner in which medical education has been conducted by the independent universities. It has still more reason to complain of the State universities. From these it ought to receive more. As long as the present industrial system prevails, the only hope is in the liberal endowment of one or two colleges. We have been waiting for Johns Hopkins for years. We have mourned the loss of a large slice of the endowment and the delay in utilizing the remainder. We have regretted the expenditure in monumental buildings of the resources which should have gone into endowment. But we still believe that the model college will be realized. We believe that the medical men of the country will advise their students to take the full science course, and then patronize the college that requires the most on entrance, and continues to require and give the most to the end of the course.

In conclusion, we would formulate the following propositions, which we believe can neither be denied nor refuted:

1. The universities, without exception, neglect their medical schools, farm them out or treat them on principles different from and inferior to those which are applied to their other departments.
2. The university medical schools compete with the poorest independent schools in their entrance examination, in their low fees, and in their short courses of study and low requirements, and thus do a great injustice to the reputation of medicine in the university.
3. The utilitarian atmosphere which pervades the medical departments of our universities, the nepotism by means of which the appointments in these schools are made, and the consequent poor pay which is given to the few teachers that are paid at all, turns away ambitious and highminded men from seeking a scholarly career in medicine.
4. In all of these directions, the State universities are most culpable.

A NEW METHOD OF OPERATING FOR TRICHIASIS, DISTICHIASIS AND ENTROPION OF UPPER LID.

Read in the Section of Ophthalmology at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, Mich., June, 1892.

BY EUGENE SMITH, M.D.,

PROFESSOR OF OPHTHALMOLOGY AND OTOLOGY IN DETROIT COLLEGE OF MEDICINE, OPHTHALMIC SURGEON TO ST. MARY'S HOSPITAL, SURGEON IN CHARGE OF ST. MARY'S FREE EYE AND EAR INFIRMARY, DETROIT, MICH.

In common with many ophthalmic surgeons I have been for many years seeking for an operation for trichiasis or distichiasis which shall offer the easiest method to the surgeon and the best result to the patient.

The Jarsche-Arlt operation and the Graefe modification of it, has for many years been considered by some as the best method of correcting the deformity, notwithstanding the facts that inflammation occasionally destroys the good effect intended, and the operation is particularly difficult when the canthi are the seat of abnormal cilia. Modifications have been offered by many operators, but most of them produce more or less cicatricial deformity of the lids. Most of us know by experience that in the transplantation of the cilia upwards (Jarsche-Arlt), it is difficult and sometimes impossible to separate all of the hair follicles from the tarsal cartilage in dividing the lid into two layers, as some may be rooted immediately *on* the cartilage or even *in* its most superficial layers, and if papillæ remain on the posterior lip, the cilia will grow again and they may not make their exit through the old canal, but often perforate the new cicatricial tissue and again appear in a faulty position causing a renewel of the ocular trouble. No degree of carefulness in operating will enable one to guard against it.

The operation to which I wish to ask your attention is one I have been making for the past five years in my private and hospital practice, which is applicable to all cases and which has, so far, given perfect satisfaction to myself and my patients. I have made the operation more than fifty times for complete and partial trichiasis. Its chief recommendations are its efficiency and ease of performance. It is made as follows: A Snellen's clamp is placed on the lid and an incision is made with a Beer's knife along the free border between the faulty and the normal cilia, somewhat as in the Jarsche-Arlt operation. The incision is carried well up to the hair follicles, two or three lines, which are plainly seen when the slight flow of blood has been removed with a sponge or pledget of absorbent cotton. If the wound does not gape, it does usually, the anterior lip is lifted with forceps, and all the hair follicles upon the cartilage are delicately touched with the fine point of the galvano-cautery or the Pacquelin cautery. Where a group of faulty cilia are attached to the anterior lip their follicles are also touched with the cautery and thus destroyed. The wound is then washed with a $\frac{1}{5000}$ solution of sublimate lotion, a pledget of cotton dipped in the same lotion is placed on the closed lid and held in place with a strip of adhesive plaster,not being removed for 24 hours, at which time the faulty cilia either drop out or are easily removed. The wound is usually found closed and healed by first intention. *The reaction is surprisingly slight. Only the region of the hair follicles* is touched with the cautery, and care must be taken not to destroy or obliterate the canals of the tarsal glands, thereby causing atrophy and contraction of the cartilage and tarsal tumors, but with proper care a successful result follows the operation though it may be necessary to repeat it partially if in an occasional case all of the faulty follicles have not been destroyed in the first operation.

In cases of partial trichiasis, the incision in the margin of the lid should simply extend a little beyond either extremity of the space occupied by the inverted hairs. The operation can be easily carried into the canthi, and does not produce any cicatricial deformity.

In mild entropion with slight incurvation of the cartilage I have several times made a *grooving* of the cartilage with the galvano-cautery, somewhat after the manner of the Streatfield operation, and in each instance with considerable success. I raise a flap of skin and muscle from the tarsal cartilage over the convex or clubbed portion and *groove* the cartilage by drawing the cautery along its entire length. I then return the flap to its place and hold it in situ with two or three points of suture. The operation is more simple than Streatfield's, as any one can see who has ever attempted to cut out a wedge shaped piece of the tarsal cartilage, *a la* Streatfield. If it is ever desirable to remove all of the eye-lashes to scalp the lid, as it were, it can be more easily accomplished with the actual cautery, and with less deformity or loss of tissue than by the old methods.

Discussion.

Dr. F. C. Hotz, Chicago:—I rise to refer to one remark the Doctor made, namely that all operations done for trichiasis leave disfiguring scars in the lids. I have tried, and as I believe succeeded, to improve the operation in trichiasis and one of my principal points has been to find an operation which will relieve the inversion of the eye lashes but also preventing disfiguring of the eye lid, a result which often followed these operations and especially the one to which reference has been made. The operation I have suggested has the advantage that cosmetically it leaves the lid in better condition than before, and the scar following the operation is put at such a place along the upper border of the lid that it is not perceptible, being hidden in the deep furrow caused by opening the lid. In my operation, we can therefore, not speak of any disfiguring scar.

As to the difficulty in dislodging all the eye lashes by splitting the lid and getting them all in the anterior flap, I must also disagree with the speaker. By making the incision far back, if necessary at the conjunctival line and by making it deep enough all the lashes can be dislodged. By splitting deeply and getting the wound to open up well by stitches and grafting in slender strip of skin, I think that you get as good results as you wish and reëstablish cosmetically the natural shape and form of the eye lid.

I do not quite understand the application of the cautery as spoken of by Dr. Smith. He spoke of treating the distorted and displaced eye lashes and leaving the normal eye lashes intact. That point I confess is not clear to me if he speaks of trichiasis. If we have the same conception of the condition spoken of as trichiasis, I think that there are no normally placed eye lashes because the border of the lid is so drawn down that all normally placed eye lashes are displaced. To destroy the abnormally placed lashes, it would be necessary to destroy them all; and in the case which has been exhibited, it looks to me as though all the eye lashes would come out.

Dr. G. C. Savage, Nashville, Tennessee:—For several years, I have done an operation for this condition. Part of the procedure is my own and I wish to briefly describe it and then you can judge whether or not it would be effective. At the first I commence by splitting the lid as Dr. Smith does then I took a double stitch which I shall describe later, so as to turn that portion of the lid out which contains the offending follicles. I found afterwards that the operation was better done by making Burow's incision. If the offending eye lashes exist throughout the lid, I make the incision from one end to the other. In addition to Burow's incision I make a cross incision at either end. These incisions involve the cartilage and everything to the skin. The stitch is all that I claim. The stitches are double. If I operate on the whole extent of the lid, after making the three incisions, I would take four stitches. I introduce the needle through the wound and bring it out in the skin just above the portion containing the hair follicles. I then pass over a portion of healthy skin and grasp another portion with the fixation forceps and transfix it with the needle. This is done from one extremity of the lid to the other before any knot is tied. The advantage which I claim is that, that portion of skin over which the thread is passed, by folding back will facilitate the turning out of that portion containing the hair follicles where the sutures are tied. The advantages are that we get wide gaping of the incision and elongation of the margins. The stitches are allowed to remain until the wedge shaped incision has had time to fill with plastic material. This is the easiest operation of any that I have performed for this condition. In my hands as well as in the hands of some others it has been very effective.

Dr. Eugene Smith, Detroit:—A word in regard to the remarks of Dr. Hotz. The operation of Dr. Hotz is apt to thicken the edge of the lid, which remains thickened and produces a certain degree of deformity which, however, is nothing in comparison with the irritation caused by the cilia. The Doctor speaks of inversion of the edge of the lid as trichiasis. I consider that entropion. I look upon trichiasis as that condition in which the edge of the lid is almost absolutely normal and we have the inverted eye lashes which spring from the normal border of the lid, the lashes being simply inverted. I also look upon other cases where the faulty lashes spring from the hair follicles and grow through the edge of the trichiasis and distichiasis. In a large majority of these cases, you can find a *space* between the inverted and normal cilia. My incision is made in this *space*. In the case shown the normal cilia were not touched with the cautery. Only the faulty follicles on the posterior lip were touched. The follicles on the anterior lip were not touched. When the dressing was removed this morning the faulty cilia came off with the dressing. Seldom do I have to remove them with cilia forceps. When this is necessary they come out without trouble. This case, gentleman, was operated npon but yesterday and in the presence of several members of this Section. The condition of the lid now, only 24 hours after the operation bespeaks more for the operation than can words of mine, as you see the case is well and no thickening or deformity exists.

BOOK REVIEWS.

The Chinese: Their Present and Future; Medical, Political, and Social. By Robert Coltman, Jr., M.D., Surgeon in Charge of the Presbyterian Hospital and Dispensary at Teng Chow Fu; Consulting Physician of the American Southern Baptist Mission Society; Examiner in Surgery and Diseases of the Eye for the Shantung Medical Class; Consulting Physician to the English Baptist Missions, etc. Illustrated with Fifteen Photo-Engravings of persons, places, and objects characteristic of China. In one handsome Royal Octavo volume. 220 pages. Extra Cloth, price, $1.75, net. Philadelphia: The F. A. Davis Co., Publishers, 1231 Filbert Street.

This little volume is filled with information that is both instructive and entertaining.

Syphilis in Ancient and Pre-historic Times. By Dr. F. Buret, Paris, France. Translated by A. H. Ohmann-Dumesnil, M.D. Philadelphia: F. A. Davis, Publisher.

This little volume is a veritable multum in parvo, embracing as it does a terse account of what has been said of this interesting subject by an almost interminable list of authors. The translator is one of the best known among American syphilographers and writers. The work is of intrinsic worth and should grace the shelves of every specialist and also of those who are interested in this field of study.

A Treatise on Diseases of the Lungs and Pleura. By the late Wilson Fox, M.D., F. R. S. Edited by Sidney Coupland, M.D., F. R. C. P. Philadelphia: P. Blakiston Son & Co., 1892.

This superb volume comprises the main literary work of one of England's best known physicians. While the subject matter is substantially the work of the distinguished author, its extent and much of its value is due to its editor.

The work is elaborate in setting forth in detail the sum of modern professional knowledge as it pertains to diseases affecting the lungs and their surrounding membrane, including diseases of the mediastinum.

Diseases of the Stomach. By Dr. C. A. Ewald, Professor of Medicine in the University of Berlin. Translated from the second German edition, by Moris Manges, A.M., M.D., with thirty illustrations. New York: D. Appleton & Co., 1892.

This work is written in the form of clinical lectures, which are intended for the use of general practitioners, and are based upon stenographic reports of remarks at the *Feriencurse fur praktische Aerzte*.

Lectures I and II, gives the author's method of examination, to determine the acidity and acids of the contents of the stomach, the digestion of albumen and starch, power of absorption and motility and the technique of the examination. Lectures III and IV, pertain to the stenoses and strictures of the orifices and to dilatation of the stomach. Lecture V, to cancer, and lecture VI, to ulcer. Lecture VII to inflammations. While three lectures are devoted to the neuroses. In lecture XII the author illustrates the practical value of modern chemical tests.

Book on the Physician Himself, and Things that Concern His Reputation and Success. By D. W. Cathell, M.D. New tenth Edition (Author's Last Revision). Thoroughly revised, enlarged, and rewritten. In one handsome Royal Octavo volume. 348 pages. Bound in Extra Cloth. Price, post-paid, $2.00, net. Philadelphia: The F. A. Davis Co., Publishers, 1231 Filbert Street.

This work by Dr. Cathell is one of the best known and popular books that has been offered to physicians during the past ten years.

NECROLOGY.

Dr. Benjamin W. McCready, Emeritus Professor of *Materia Medica* of Bellevue Hospital Medical College, died in New York City, on Wednesday the 10th inst. He was one of the senior graduates of old Barclay Street School, being of the class of 1835. He was over half a century in practice, leaving behind the record of a useful and honorable career. He was a good teacher, having filled a professorship of *Materia Medica* in the College of Pharmacy before 1860, at which time he united with Austin Flint, James R. Wood, Barker and others in founding the junior college at Bellevue. McCready was for many years a physician to Bellevue Hospital. During his prime there were few therapeutical chairs that drew better classes than his; he withdrew from the active duty of that chair in 1872 and was succeeded by Dr. William Hammond. He was a member of the Association in 1853, and about that time he was the editor of the *New York Journal of Pharmacy*. Dr. McCready retired from practice about seven years ago.

Dr. A. R. Brown Horner, Surgeon and Medical Director U. S. Navy, died August 8, 1892, at Warrenton, Va., age 88. Dr. Horner had served sixty-five years and six months in the navy and at the time of death was the oldest medical officer, with the relative rank of commodore in the navy. He was three times appointed by the Executive, Surgeon-in-Chief of various squadrons, for many years was appointed on the Naval Medical Boards, by seniority became Surgeon General of the Navy, was the author of "Cruise in the Mediterranean" of "Medical Topography of Brazil and Uruguay" and of "Naval Practice," the latter one of the first publications of the kind in this country. He was honorary member of the Philadelphia Medical Society and corresponding member of the National Institute at Washington. In private, social and public life Dr. Horner lived up to the standard of a noble manhood. He neither used stimulants nor tobacco. During his long, eventful life he displayed an unswerving loyalty to the Federal Union and *mens sana in corpore sano*. He gave testimony to his faith in the Gospel of our Lord Jesus Christ as the ground of his hope of salvation hereafter.

The American Medical Association.—The recent meeting at Detroit was probably one of the most important and best organized which the Association has ever held. Considerably over 1,000 medical men were present from all parts of the States, and not only the general meetings, where what may be called medical politics are for the most part discussed, but also the meetings of the various Sections, which occupied themselves with matters of purely professional or scientific interest, were conducted with vigor and energy which showed how intent the members were on the various matters which had to be discussed. There were in all twelve Sections, each with a chairman and secretary of its own, and although occasionally a meeting of one or more Sections had to be adjourned out of consideration for the absorbing interest which surrounded a few of the general meetings, the amount of work which was accomplished was by no means small.

The meeting was opened in the Detroit Opera House. The stage was beautifully decorated with flowers and palms, and the house was filled with an audience which was evidently keenly interested in all the proceedings. After Bishop Davies had offered prayer and General Alger had in a few appropriate words welcomed the Association to Detroit the President of the year, Dr. Marcy, of Boston, delivered an address, the subject being "Evolution in Medicine." This somewhat technical title scarcely conveys an adequate idea of the scope and bearing of the interesting address which was delivered. It was indeed more a description of the development of the American Medical Association and an indication in outline of the direction in which it should proceed in the future, with the view of drawing closer together the various associations and societies throughout the country and of strengthening the hands of those who are endeavoring to press on reforms in regard to medical matters. One subject was referred to in the address in which the orator evidently carried with him his entire audience—viz., the proposed establishment of a national board of health presided over by a secretary of public health who should be *ex officio* a member of the Presidential Council. Such a board would take cognizance of all that affects the public health of the community, especially of epidemic and infectious diseases, and there seemed to be a universal consensus of opinion that such a central board would, in coöperation with the State boards of health, be the means not only of enforcing sanitary regulations but also of educating the people to recognize their importance and desirability.—*London Lancet*, Aug. 6.

The following ordinance to prevent empiricism was recently enacted in the town of Effingham, in Illinois. Similar enactments in all village and town corporations would speedily locate all traveling charlatans. To locate such people, either drives them out of business or to the large cities.

An Ordinance to Prevent Empiricism.—Be it ordained by the City Council of the City of Effingham: That it shall be unlawful for any itinerant physician or itinerant vendor of drugs or medicines, to practice medicine in any of its branches, or sell or dispose of any drug, medicine, nostrum or ointment intended for the treatment of disease or injury, or to open an office for such purpose, or to announce to the public in any way an intention to practice medicine, or to sell or dispose of such drug, medicine, nostrum or ointment within the corporate limits of this city: Provided, That nothing in this ordinance shall be so construed as to prohibit any reputable physician or surgeon from any other place being called to see a particular case or family, or to do a particular operation in said city.

Any person violating this ordinance shall be subject to a penalty of not less than fifty ($50) dollars nor more than one hundred ($100) dollars.

Dated this second day of August, A. D. 1892.

Approved: J. B. Walker,
Mayor.

Attest: W. M. Stewart.

Dilute Hydrobromic Acid (15-20 minims) is prescribed by Dr. B. W. Richardson with digitalis infusion (½ ounce) for noises in the head, with throbbing.

THE
Journal of the American Medical Association
PUBLISHED WEEKLY.

SUBSCRIPTION PRICE, INCLUDING POSTAGE:
PER ANNUM, IN ADVANCE $5.00
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any time and be sent to
THE JOURNAL OF THE AMERICAN MEDICAL ASSOCIATION,
No. 68 WABASH AVE., CHICAGO, ILLINOIS.

All members of the Association should send their Annual Dues to the Treasurer, RICHARD J. DUNGLISON, M.D., Lock Box 1274, Philadelphia, Pa.

MEMBERSHIP IN THE AMERICAN MEDICAL ASSOCIATION.

This is obtainable, at any time, by a member of any State or local Medical Society which is entitled to send delegates to the Association. All that is necessary is for the applicant to write to the Treasurer of the Association, Dr. Richard J. Dunglison, Lock Box 1271, Philadelphia, Pa., sending him a certificate or statement that he is in good standing in his own Society, signed by the President and Secretary of said Society, with five dollars for annual dues. Attendance as a delegate at an annual meeting of the Association is not necessary to obtain membership. On receipt of the above amount the weekly JOURNAL of the Association will be forwarded regularly.

SATURDAY, AUGUST 27, 1892.

MEDICAL SIDE OF CAPITAL PUNISHMENT.

The recent great advance in scientific knowledge of criminals and criminality, has given new interest to the question of capital punishment. Practically the subject has passed from the realm of morals, sentiment and law into that of science. The old time arguments pro and con, are childish when viewed from the side of modern science. The physician who is not familiar with the practical teachings of the modern views of crime has much to learn. The question of capital punishment to-day, is simply that of brain, health and soundness of the criminal. To take the life of a diseased and brain degenerate man is no punishment, and no deterrent of crime. The original object of capital punishment is defeated in such instances. The theory of revenge and retaliation in the punishment of crime, has no support in modern civilization, the question of responsibility is a medical one, beyond the theory and morals. The best authorities assert from careful physical study of criminals, that they as a class, have abnormal brains and brain structure; also marked degenerate types of organism. Deviation from the normal, and reversions backward to some lower stage of savagery. They also possess conditions of instability of brain force, and predispositions to diseases and morbid impulses, with feeble or absent moral powers, to recognise the higher consciousness of right and wrong. Criminals are not only defects externally, but are neurotics and irregular in their mentality, and suffer from many and complex disorders. The abnormalities of organism and structure, are followed by abnormalities of acts, with feeble power to return to a normal type.

A clinical study of criminals reveals a great variety of constitutional effections unnoticed before. Hereditary predispositions, palsies, traumatisms, brain malformations, and a constant tendency to recede from a healthy normal type. All forms and degrees of insanity, and brain weakness are constantly present. In view of these and many other general facts, it is literally impossible to determine the degree of health and capacity to *act* sanely and normally in the criminal. A committee of the New York State Medical Society has made a very able report on this subject recently. This report is purely scientific, and confined entirely to the question of the possible brain health and the capacity of the criminal to have done otherwise. The conclusions of this very elaborate report indicate that criminals have perversion of judgment and will for which there are many causes. These causes are either congenital or acquired. When congenital they develop progressively *from disease or cerebral impairment*, and when acquired arrive from injury, disease and external favoring causes. Cerebral anomalies and central brain lesions, are not accessible to ordinary investigation. Degrees of dementia and various obscure forms of insanity may exist for a long time unnoticed, and the moral or higher brain centers exhibit the only evidence of departure from health. Irrespective of all theory and opinion, these and other facts are so numerous and well attested, proving the disease and unsoundness of the criminal, that his punishment by death for any crime is of doubtful value from every scientific point of view. "The committee with knowledge of the physiological and psychological facts, and the absolute impossibility of making a positively safe diagnosis in every case of alleged crime or the presumable disease or anomaly of the criminal, expresses its opposition to the perpetuation of capital punishment, and its hope that means will be found to protect the community by less uncertain and more humane methods." This aptly expresses the latest voice of science. Appeals to the physical facts in the history of criminals, will give far safer standards to judge from, than theory or sentiment. Physicians should always be found on the scientific side of such questions. If the criminal is always sick and diseased, this fact will come to surface despite all theory and opposition. Physicians of all others should be students and teachers of public opinion in this. Capital punishment, whether barbaric or human, is a question of facts, that are within the domain of every medical man, and must be finally settled along this line.

IMPURE AMERICAN BROMIDES.

HELBING'S *Pharmacological Record* for May has an important statement concerning the undue proportions of potassium chlorate that are found in the bromides of American makers. An examination made by HELBING and PASSMORE show that it is a serious matter to buy the potash salt, at the present time, without having it carefully analyzed as to the percentage of chlorides it may contain. The English drugs in their original packages, however, are pronounced as safe. Samples of those products did not yield higher than .13 per cent. of chlorate of potash, while four American samples carried from 4.52 to 5.96 per cent. The American Pharmacopœia permits of not more than three per cent., and the German about one per cent. The importance of purity in a drug of this nature is very great, and will receive the earnest heed of neurologists everywhere.

TREATMENT OF PNEUMONIA.

The treatment of pneumonia is ever a subject for consideration. In a recent clinical lecture, DR. ANDREW H. SMITH[1] has again given his views upon this subject. DR. SMITH's ideas upon the employment of arterial relaxants in the treatment of pneumonia, have been given to the profession before, but do not seem to have attracted as much attention as they really deserve.

It is generally understood that in pneumonia, the local pulmonary lesion, and the constitutional manifestations are not necessarily in harmony. That is, that while an extensive local trouble may occur concurrently with severe general symptoms, yet the reverse may obtain, and great lung consolidation not be accompanied by serious general symptoms, or there may even be slight local trouble, with the most dangerous general condition.

Each of these two general factors is to be considered in determining the plan of treatment to be employed in a given case of pneumonia.

Extensive local trouble in the lungs reacts mechanically upon the heart, but as DR. SMITH has pointed out, it is the right heart which is involved, *and not the left.*

As the pulmonary circulation through the involved lung becomes more and more retarded, the right heart makes more strenuous efforts to overcome the obstacle, the tension in the pulmonary artery becomes higher, and the second pulmonary sound at the base of the heart becomes more accentuated. As the right heart flags in its work, the veins become overfull, and cyanosis makes its appearance. The left heart acting synchronously with the right, but *without a great obstacle before it, adds to the difficulty* by keeping the systemic veins over full. Under these circumstances it becomes necessary to relieve the right heart as much as possible. It is impossible to remove the obstruction in front of it, but much may be done to relieve the pressure of blood behind it. By relaxing the arteries, more blood is retained *in them, and the venous pressure diminished.* The agents employed for relaxing the arteries are principally the nitrites, and of these, amyl nitrite, and nitroglycerine act most rapidly, and sodium nitrite, the most persistently. Aconite and veratrum have the same power of relaxing the arterial tension, as does also the liquor ammoniæ acetatis. For the relief of the cyanosis, the inhalation of oxygen gas acts promptly, and it is hard to believe after seeing its action, that its good effects are confined to oxidizing the blood. When grave constitutional symptoms are present, the left heart is also in danger, and must be held up, by stimulants. Of these alcohol and strychnia are probably the best, as they act without increasing the arterial tension. Digitalis should always be used with great caution, because it not only stimulates the heart directly, but also stimulates it through the contraction of the arterioles which it produces. Whenever used it should be guarded by the simultaneous use of an arterial relaxant, so that only its direct stimulation of the heart may appear. This is particularly true when the extent of lung tissue involved is great, and less so when the local lesion is slight. During the progress of the case, the condition of the left heart is watched at the pulse, while the condition of the right heart is determined by the character of the second pulmonary sound, by the cyanosis, and by the character of the respiration, in relation to the amount of lung consolidated.

CHOLERA.

The epidemic of Asiatic cholera in Russia continues its ravages in that country. More than 6,000 new cases have been reported almost every day for more than a month, with a mortality rate of nearly or more than half that number. Estimates based on official statistics indicate that more than 35,000 deaths from cholera have occurred in Russia during the present summer. The epidemic of choleriform diarrhœa in Paris has nearly disappeared. The disease was mainly in the suburbs, and almost wholly among the rag-pickers and those who were living under very bad hygienic conditions. The total number of deaths reported is about 400. The prevention of the further spread of the disease is due to the strict measures adopted by the government authorities.

In Berlin and other German cities and towns the most stringent sanitary measures have been adopted to prevent the disease obtaining a foothold in that country. The police authorities have issued notices which prohibit the importation into or passage through the lines of travel of all old clothes, bed or other linen, rags, etc., fruit, fresh vegetables, butter and cheese from Russia. The clothes and luggage of travelers are to be disinfected.

The German Government Department for medical matters has addressed circulars asking for the names of physicians, especially of those in posts, hospitals and universities, who are competent and ready to carry out bacteriological examinations in connection with cases of supposed cholera, and who are willing to assist the government medical officers in case cholera should break out and become epidemic.

---

[1] International Medical Magazine, July, 1892.

We are pleased to notice that our own government through its Consular Officers is kept well informed of the progress of cholera in European and Asiatic countries and is alive to the necessities of a strict quarantine against all infectious material.

As we go to press the cable informs us of the spread of cholera to Havre. This important European seaport is in almost constant touch with this country through common commercial and other interests, and it will be a high tribute to the value of sanitary science if our quarantine officers are equal to the occasion and show the possibility of affording protection to our people. The lateness of the season is favorable, but it should not be forgotten that previous epidemics of this disease have made their first appearance in October and as late as December.

EDITORIAL NOTES.

Note.—The paper by Prof. H. J. Herrick, M.D., on the Relative Interdependence of Organs of the Body in Health and Disease, published on page 221 of our last issue was read before the Section on Medicine, and not by title as indicated in the heading. The author's initials are H. J., instead of J. B.

Prevention of Puerperal Sepsis, on page 205 of the issue of Aug. 13, should have been credited to the editorial department of the *Buffalo Med. Journal.*

Our August Vacation Time.—The editor of the *Maryland Medical Journal,* in considering the advisability of his taking a summer's outing, falls into a monologue like the Prince of Denmark, and murmurs: "To skip or not skip, that is the question. Whether 'tis better in town to suffer the heat and swelter of the month of August, or to take grip in hand and migrate to some mountain clime, or to some pebbled beach? To dive, to swim, to loaf, but in that loaf, what images of science come forth—the clustered rods of typhobacillus, lurking in myriads in the hotel well, borne on the seepage of some neighboring cesspool; the organisms that thrive in dysentery; the germs of common everyday sepsis, each form more toxic than the other. Coiled on the mountain lurks the dreaded rattler, with lethal hypodermic ready; or at the seaside, in those hired bathing garments hide the germs of grave infections—of eczema, chancroid and secondary—ready to fasten on the fretted skin."

These apparitions of uncertain ills puzzle the will, and make him rather bear the city trials he has known, than fly to country ones which mayhap are worse: Thus science doth make coward of the editor, and he grows sicklied o'er with the pale cast of doubt and excessive transpiration from the heat. The newly developed, almost virgin fields of North Carolina should be good for his complaint.

ILLINOIS STATE BOARD OF HEALTH.

ABSTRACT FROM THE MINUTES OF THE MEETING OF JULY 27, 1892.

1.—Colleges requiring four (4) or more years of study and four (4) or more terms of lectures as conditions of graduation:

Chicago Medical College, Medical School, Northwestern University, Chicago, Ill.
Harvard University Medical School, Boston, Mass.
Boston University School of Medicine, Boston, Mass.
Department of Medicine and Surgery, University of Michigan, Ann Arbor, Mich.
Homeopathic Medical College, University of Michigan, Ann Arbor, Mich.
Leonard Medical School, Raleigh, N. C.
McGill University, Faculty of Medicine, Montreal, Que.[1]
University of Toronto, Faculty of Medicine, Toronto, Ont.
Ecole de Medicine et de Chirurgie, Montreal, Que.
Trinity Medical College, Toronto, Ont.
Laval University, Medical Departments, Quebec and Montreal, Que.
Royal College of Physicians and Surgeons, Kingston, Ont.
Halifax Medical College, Halifax, N. S.
Dalhousie University, Faculty of Medicine, Halifax, N. S.
University of Bishop's College, Faculty of Medicine, Montreal, Que.
Medical Department of Western University, London, Ont.
Woman's Medical College, Toronto, Ont.
Women's Medical College, Kingston, Ont.
Manitoba Medical College, Winnipeg, Man.

2.—Colleges requiring four (4) or more years of study and three (3) terms of lectures as conditions of graduation:

California Medical College, San Francisco, Cal.
College of Medicine, University of Southern California, Los Angeles, Cal.
Rush Medical College, Chicago, Ill.
Hahnemann Medical College and Hospital, Chicago, Ill.
Bennett College of Eclectic Medicine and Surgery, Chicago, Ill.
Woman's Medical College, Chicago, Ill.
Chicago Homeopathic Medical College, Chicago, Ill.
College of Physicians and Surgeons, Chicago, Ill.
Medical College of Indiana, Indianapolis, Ind.
Central College of Physicians and Surgeons, Indianapolis, Ind.
Medical Department, State University of Iowa, Iowa City, Ia.
College of Physicians and Surgeons, Keokuk, Ia.
Iowa Eclectic Medical College, Des Moines, Ia.
Hospital College of Medicine, Louisville, Ky.
College of Medicine and Surgery, of the University of Minnesota, Minneapolis, Minn.
Homeopathic Medical College of Missouri, St. Louis, Mo.
American Medical College, St. Louis, Mo.
University Medical College, Kansas City, Mo.
Eclectic Medical College of the City of New York, New York, N. Y.
Medical College of Ohio, Cincinnati, O.
Eclectic Medical Institute, Cincinnati, O
Cincinnati College of Medicine and Surgery, Cincinnati, O
Miami Medical College, Cincinnati, O.
Women's Medical College, Cincinnati, O.
Medical Department Willamette University, Portland, Or.
University of the State of Oregon, Medical Department, Portland, Or.
Dartmouth Medical College, Hanover, N H.

Colleges requiring three (3) or more years of study and three (3) terms of lectures as conditions of graduation:

Cooper Medical College, San Francisco, Cal.
Medical Department, University of California, San Francisco, Cal.
Hahnemann Hospital College, San Francisco, Cal.
University of Denver, Medical Department, Denver, Col.
Medical Department. University of Colorado, Boulder, Col.
Gross Medical College, Denver, Col.
Yale University, Department of Medicine, New Haven, Conn.
National Medical College, Washington, D. C.
University of Georgetown, Medical Department, Washington, D. C.
Howard University, Medical Department, Washington, D. C.
Medical Department, National University, Washington, D. C.
Fort Wayne College of Medicine, Fort Wayne, Ind.
Iowa College of Physicians and Surgeons, Des Moines, Ia
Homeopathic Medical Department, State University of Iowa, Iowa City, Ia.
Medical School of Maine at Bowdoin, Brunswick, Me.
University of Maryland, School of Medicine, Baltimore, Md.

The following is a partial list of medical colleges the diplomas of which are required to be supplemented by examination:

Medical College of Alabama, Mobile, Ala.[2]
Medical Department Arkansas Industrial University, Little Rock, Ark.[3]
Medical College of Georgia, Augusta, Ga.[2]
Atlanta Medical College, Atlanta, Ga.[2,3]
Woman's Medical College of Georgia and Training School for Nurses, Atlanta, Ga. (First session 1889–1890.)
Southern Medical College, Atlanta, Ga.[2]
Physio-Medical College, Chicago, Ill. (First session 1891–92.)
Eclectic College of Physicians and Surgeons, Indianapolis, Ind. (First session 1890–91.)
Keokuk Medical College, Keokuk, Iowa. (First session 1890–91.)
Kansas Medical College, Topeka, Kan. (First session 1889–90.)
University of Louisville, Medical Department, Louisville, Ky.[3]
Kentucky School of Medicine, Louisville, Ky.[3]
Louisville Medical College, Louisville, Ky.[3]
Medical Department, Tulane University of Louisiana, New Orleans, La.[2,3]
Medical Department, New Orleans University, New Orleans, La. (First Session 1889–90.)
Baltimore University School of Medicine, Baltimore, Md.[3]
College of Physicians and Surgeons, Boston, Mass.[3]
Michigan College of Medicine and Surgery, Detroit, Mich. (First session 1888–89.)
St. Louis College of Physicians and Surgeons, St. Louis, Mo.[3]
Northwestern Medical College, St. Joseph, Mo.[3]
Ensworth Medical College, St. Joseph, Mo.[3]
Beaumont Hospital Medical College, St. Louis, Mo.[3]
Marion-Sims College of Medicine, St. Louis, Mo.[3] (First session 1890–91.)
Kansas City Homeopathic Medical College, Kansas City, Mo. (First session 1888–89.)
Northwestern Ohio Medical College, Toledo, O.[3]
Cleveland Medical College, Cleveland, O. (First session 1890–91.)
Medical Department, University of Nashville and Vanderbilt, Nashville, Tenn.[2,3]
Medical Department, University of Tennessee, Nashville, Tenn.[3]
Memphis Hospital Medical College, Memphis, Tenn.[2,3]
Chattanooga Medical College, Chattanooga, Tenn. (First session 1889–90.)
Tennessee Medical College, Knoxville, Tenn.[2,3] (First session 1890–91.)
Hannibal Medical College, Memphis, Tenn.[3] (First session 1889–90.)
Texas Medical College and Hospital, Galveston, Texas.[2] (First session 1888–89.)
Medical College of Virginia, Richmond, Va.[3]
University of Virginia, Medical Department, Charlotteville, Va.[3]

There are in addition to the foregoing a number of other institutions whose requirements as to periods of study and attendance upon lectures, facilities for practical anatomy and for hospital and clinical instruction are so inadequate as to preclude their graduates from any standing before the Board, and there are some half-dozen or more others which are under investigation by the Board.

REPORT OF THE COMMITTEE OF THE STATE BOARD OF HEALTH OF ILLINOIS ON MEDICAL EDUCATION AND MEDICAL COLLEGES.

Offices of the Board,
Springfield, Ill., July 27, 1892.

To the President:

Sir:—Your committee, appointed to report on the practical workings and results of the resolution of the Board, adopted July 8, 1887—by which it was required that colleges, to be held in good standing for the purposes of the Illinois Medical Practice Act should, after the sessions of 1890–91, require four years of professional study, including any time spent with a preceptor, and three regular terms of lectures, as conditions of graduation, and should otherwise conform to the schedule of minimum requirements theretofore required by the Board, begs leave to submit the following:

In the last report on medical education and medical colleges, 1891, by Dr. John H. Rauch, to the Illinois State Board of Health, there is given, on pages 170–2, a list of medical colleges in the United States and Canada then in operation. The total is 148, but of this number 4 do not grant degrees, 3 have suspended, and 4 are not recognized by the Board.

An analysis of the remaining 137 colleges given in Dr. Rauch's list, and which embraces, substantially, all the established medical institutions in this country, is here submitted.

There are 19 colleges which require four (4) or more years of study and four (4) or more terms of lectures as conditions of graduation; there are 27 which require four (4) or more years of study and three (3) or more terms of lectures as conditions of graduation; there are 55 which require three (3) or more years of study and three (3) terms of lectures as conditions of graduation; there are 16 which require only three (3) years of study and only two (2) terms of lectures as conditions of graduation; and 5 are silent as to number of years of study, and graduate on only two (2) terms of lectures.[4]

This showing, it is submitted, is a most encouraging one. Over one-third of the established medical institutions of the country now exact four (4) or more years of professional study and three (3) or more terms of lectures as conditions of graduation; 45 per cent. more require three (3) or more years of professional study and three (3) regular terms of lectures.

---

[2] Requires no entrance examination.

[3] Graduates on two terms of lectures.

[4] This accounts for 122 of the 137. Of the remaining 15, 12 are thrown out of the analysis because, being of less than five years' existence, they cannot be said to have established a standing. They comprise four 4-year and 3-term schools; four 3-year and 3-term schools; three 3-year and 2-term schools; and one 2-term school. It will be seen, therefore, *that* including them would not affect the proportions as obtained in the 122 established medical colleges.

Two 4-year and 3-term colleges and one 3-year and 3-term college are also thrown out, because under investigation by the Board as to their standing.

That is to say, nearly eighty-three (83) per cent. have complied, substantially, with the resolution of the Illinois State Board of Health of July, 1887.

Of the remaining 17 per cent. all but two are Southern schools—the exceptions being the College of Physicians and Surgeons of Boston, Mass., and the Northwestern Medical College of Toledo, O.

In view of these results of the operation of the July, 1887, resolution, as shown by this analysis, it is hereby recommended that, in the discharge of the responsibility with which the Board is vested by the General Assembly—to determine the good standing of legally chartered medical institutions, the diplomas of which may be presented to the Board as the warrant for the State certificate which is "conclusive as to the right of the lawful holder of the same to practice medicine in this State"—the following rules be adopted:

Rule 1.—Any established, legally chartered medical institution shall be held to be in good standing, for the purposes of the Illinois Medical Practice Act, which conforms to the course and period of study, the number, character and length of lecture terms, the duration of attendance on hospital and clinical instruction, and the other requirements of a medical education which obtain as the practice of a majority of the established medical colleges of the United States and Canada.

Rule 2.—No medical college can be held to be in good standing until it has established its claim to such standing by an active existence of not less than five (5) years, and then only upon compliance, during such period, with the terms of Rule 1, and by its work and the character of its graduates as determined by the examination of the Board.

Rule 3.—Graduates of medical colleges which do not fully conform to the practice of the majority of established medical institutions in good standing may, in the discretion of the Board, obtain State certificates upon passing examinations in writing in the branches of the usual medical college course, to wit: anatomy, physiology, chemistry, materia medica and therapeutics, theory and practice of medicine, pathology, surgery, obstetrics and gynecology, hygiene and medical jurisprudence.

Graduates of medical schools of less than five (5) years' existence, but which conform to the practice of the majority of established medical institutions in good standing, may, in like manner and in the discretion of the Board, obtain State certificates upon passing examinations in the branches of the usual medical college course as above recited.

No fee shall be charged for the examinations provided for by this rule.

Rule 4.—Any medical institution which is not recognized by the American Medical College Association, or by the American Institute of Homœopathy, or by the National Eclectic Medical Association, or by the American Association of Physio-Medical Physicians and Surgeons, as the case may be, shall be declared and held to be not in good standing for the purposes of the Illinois Medical Practice Act.

Your committee would add that it believes the necessity and propriety of the above rules are so obvious that no argument is needed for their adoption.

Concerning Rule 3, however, it may be observed that its effect would be to avoid individual hardship in the case, for example, of a graduate of a college which had not yet established its good standing by the necessary period of active existence, or in the case of a graduate of an established college which had failed to conform fully to the requirements of the Board. Instead of punishing the individual graduate for the immaturity or the laches of his alma mater, he would be entitled to a State certificate on demonstrating his fitness to be entrusted with the "interests of the life and health of the citizens of the State" as a practitioner of medicine.

And this, it is conceived, is the primary and essential object of the Illinois Medical Practice Act.

All of which is respectfully submitted.

A. L. Clark.
W. R. Mackenzie.
D. H. Williams.

SELECTIONS.

Heroes and Martyrs.—We deeply regret to have to announce the death of Dr. Tilden from typhoid fever, contracted, it is believed, from bacillary infection, arising in the course of a research which he was conducting on the bacillus of typhoid. Dr. Tilden was intending to bring some of the results of his pathological studies before the meeting of the British Medical Association now in progress at Nottingham. It will be remembered that Dr. Mahomed similarly fell a victim to his scientific and self-sacrificing ardor. Such incidents in the history of the devoted laborers in medical research have been only too sadly common of late. Three students of St. Thomas' have suffered the dangers which the modern heroes of the physiological and pathological laboratory have to face. One—Mr. Lucas—died from infection in studying puerperal septicæmia; another becoming infected with local tuberculosis, was saved by amputation of the finger, but not without serious constitutional injury. Dr. Spear, one of the ablest of the inspectors of the Local Government Board, died not long since from constitutional infection with anthrax, of which he was making a careful prophylactic study; and another inspector, Dr. Monckton Copeman, only the other day came nigh to a catastrophe from a similar cause. The silent heroism of the medical scientist who pursues knowledge amid much surrounding peril is often passed unnoticed, but is none the less worthy of honor and respect.—*Brit. Med. Journal.*

The Present Attitude of the Medical Profession in Regard to the Surgical Management of Spinal Injuries.—This question of the surgical treatment of those lesions of the medullary substance and the osseous structure of the spine, is one of enormous importance, and should be definitely settled by those whose practice, study and observation properly qualify them to speak.

Watson, at the Nashville meeting of the American Medical Association, presented an exhaustive and analytical monograph which has gone a great way to define the relation between physical traumatic lesions and subsequent pathological changes, as revealed through an extensive series of injuries inflicted on etherized dogs.

Manley, of New York, followed him with a series of thirty cases of serious spinal lesions of every degree of severity, reported and described before the New York Medical Association; besides, in another full and systematical monograph the following year, at the Washington meeting of the American Medical Association. The latter fully and unequivocally endorses the conclusion of Watson from his observations on the living subject, and concludes that Erichsen's "railway spine" is a purely mythical entity.

Let the contesting brethren test their mettle in this controversional warfare; but what we want is the "searchlight thrown on." The simple question is: In serious spinal injuries, which cause paralysis and lead to the suspicion of fracture or displacement, do modern surgical methods permit us to safely make an exploratory incision? In other words, make a simple, a compound fracture; remove the fragments if there are any, or expose the cord.

The profession is ominously silent on this question. In this immense country there must be many broken backs in the course of the year. But, we hear nothing from them except now and again when an odd one has been successfully treated by surgical intervention. What becomes of the rest?

Are the failures relegated to quiet oblivion, or are operators reluctant to increase their mortuary records?—*Times and Register.*

Poisoning by Ichthyol.—The increasing employment of ichthyol in the treatment of various conditions such as sprains, lymphatic enlargements, and certain diseases of the skin, renders a full acquaintance with its powers as a medicinal and toxic agent necessary on the part of the general practitioner and specialist. It is probable that there are few drugs which, applied externally, can exert so favorable and rapid an effect as ichthyol. Many physicians, who have never employed it, can scarcely be made to believe the rapid changes which take place in diseased tissues under its free and proper employment.

We have already pointed out elsewhere the singularly good results which follow its inunction about joints which are inflamed by gout and subacute rheumatism. In association with salicylates, there is certainly no application which gives as great relief to the patient as does ichthyol. That the drug is capable of producing poisonous symptoms seems to be proved by the report of an Italian physician, Dr. Bergerio, who has employed the drug as an intrauterine injection after curetting the uterus. Shortly after the injection the patient complained of a fishy taste in the mouth and of the odor of ichthyol. The pulse became exceedingly rapid, and symptoms of collapse came on with great rapidity. These symptoms, however, disappeared in about twelve hours. Naturally, Bergerio concluded that this case of intoxication was due to the absorption of the drug from the exposed surface of the uterus, and he reports that his colleague, Peroni. observed, in another case, vomiting, headache, convulsions, and diarrhœa after the employment of ichthyol in a patient who was suffering from prurigo.—*Therapeutic Gazette.*

Adulterated Iodoform Gauze.—According to the *Chemist and Druggist* for June 11, 1892, one of the German analytical laboratories has detected an adulterated iodoform gauze, which was labelled "iodoform gauze, thirty per cent." It contained eight per cent. of iodoform, and the color had been heightened by a nitrated derivative of phenol.

To detect this adulteration, the gauze should be plunged in water, when the water becomes of a yellow color. Pure iodoform gauze does not yield its color to water.

Treatment of Blenorrhagia with Permanganate of Potash. Prof. Reverdin (*Gaz. Hebdom. Scien. Med.*).—A solution is made of 1 to 5000—two grains to the pint—and, by means of a small catheter passed down to the bulb, the urethra is thoroughly irrigated with about a quart of it. This may be done with a syringe, but better by an elastic tube attached to a little cistern suspended above the patient's head. To avoid staining his linen, which may lead to disastrous revelations, the patient stands up and passes the penis through a hole in a waterproof apron tied round his waist. The injection should be used at the temperature of 100° F., and twice a day. No medicine is given, and a cure should be effected in from three days to a fortnight, generally in a week.

MISCELLANY.

The Medical Society of Virginia, will convene for the 23d annual session at Alleghany Springs, Montgomery Co., Va., September 13, 1892.

On Wednesday morning, September 14, at 10 o'clock, the Society will be called to order. Business of a general character will be in order until 11 o'clock, when the President, Dr. H. Gray Latham, of Lynchburg, will deliver the annual address of the President.

Papers will be:

Appendicitis, by Dr. Wm. Edward McGuire, Richmond, Va.

Laparotomy and the Good Accomplished by it in Gynecology, by Dr. R. S. Martin, Stuart, Va.

Some New Ideas that are Old, by Dr. S. W. Dickinson, Marion, Va.

Necessity of Prompt Action in Cases of Placenta Prævia, With Report of Cases, by Dr. L. H. Keller, Luray, Va.

Some Ocular Diseases in Children, by Dr. Phillip Taylor, Richmond, Va.

Mysteries of Medicine, by Dr. C. W. Gleaves, Wytheville, Va.

Injuries of the Knee; Their Treatment and Results, with Special Reference to the Prevention and Cure of Suppurative Action in and About the Joint, by Dr. M. W. O'Brien, Alexandria, Va.

In response to the postal issued during August, 1892, the following have responded:

The Causative Relations of Bacteria to Disease, by Dr. C. M. Blackford, Lynchburg, Va.

Common Sense in the Treatment of Discharge from the Ear, by Dr. Alexander Duane, No. 25 E. 31st St., New York, N. Y.

Some Uses of the Iodides, by Dr. L. G. Pedigo, Roanoke, Va.

Cataract, Dr. Joseph A. White, Richmond, Va.

Some Remarks on the Continued Administration of Digitalis, Illustrated by the Report of a Case, by Dr. F. M. Brooks, Fairfax Station, Va.

Also in response to invitations duly issued, the following invited guests have promised papers:

Uterine Hæmorrhage and Present Method of Treatment, by Dr. A. Vander Veer, Albany, N. Y.

Surgical Management of Fibroid Tumors of the Uterus, by Dr. Joseph Price, Philadelphia, Pa.

Modern Electrical Methods as a Substitute for Surgery in Certain Pelvic Affections, by Dr. G. Betton Massey, Philadelphia, Pa.

Sexual Hypochondriasis and Perversions of the Genesic Instinct, by Dr. Irving C. Rosse, Washington, D. C.

What Shall Be Done With the Imbecile, by Dr. Samuel J. Fort, Ellicott City, Md.

Hypnotism as a Therapeutic Agent, by Dr. Wm. Lee Howard, Baltimore, Md.

The Twentieth Annual Meeting of the American Public Health Association will be held at the City of Mexico, Mexico, November 29, 30, and December 1 and 2, 1892. The Mexican Government has interested itself in the work, thereby assuring the success of the meeting. All the details are in the hands of Federal officers of the Republic of Mexico. The General Government has requested every State to send delegates. Invitations have also been extended to Central and South America. The session will continue four days, and owing to the expected large number of papers the Association will probably, for the first time, do its work in Sections. Prominent sanitarians and scientists from the United States, Canada, Mexico, and the Central and South American Republics will take an active part in the meeting.

The American Association of Obstetricians and Gynecologists will hold its fifth annual meeting at the Lindell Hotel. St. Louis, Tuesday, Wednesday and Thursday, September 20, 21 and 22, 1892. The President, Dr. A. Vander Veer, of Albany, N. Y., wishes it understood that all members of the medical profession interested in the subjects discussed, or who are friends of the Association, even though not especially interested in its branch of work, are most cordially invited to attend the several sessions.

The Lindell Hotel will be the headquarters of the Association during the meeting, and has a convention hall which will provide ample accommodation for its sessions.

By order of the Executive Council.

William Warren Potter, Sec'y.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from August 13, 1892, to August 19, 1892.

Capt. Adrian S. Polhemus, Asst. Surgeon U. S. A., is granted leave of absence for one month, to take effect about September 1, 1892.

Capt. Marcus E. Taylor, Asst. Surgeon U. S. A., leave of absence granted on surgeon's certificate of disability is extended four months on surgeon's certificate of disability.

Official List of Changes in the Medical Corps of the U. S. Navy, for the Week Ending August 20, 1892.

P. A. Surgeon Richard Ashbridge, detached from Navy Yard, New York, and wait orders.

ORIGINAL ARTICLES.

METHOD AND RESULTS OF SIMPLE EXTRACTION OF CATARACTS.

Read in the Section of Ophthalmology, at the Forty-third Annual Meeting of the American Medical Association, held at Detroit, June, 1892.

BY H. KNAPP, M.D.,
OF NEW YORK.

Gentlemen:—When your President honored me with an invitation to this meeting and to read a paper, I thought that a description of simple extraction and its results, good and bad, might perhaps be more acceptable to the Society than any other subject I could have chosen.

I shall confine my remarks to the method practiced, and the results obtained, by myself during the last six years, *i. e.*, since I adopted simple extraction as the general operation. My views and rules are based on the experience gained by 623 simple extractions, intercurrent with which 60 combined extractions (about 10 per cent.) were made. No cases are omitted except such traumatic and complicated cataracts in which the cataract was the minor evil, for instance partial detachment of the retina complicated with cataract, and the like.

The *method of operating* such as I practice it, though scarcely offering anything absolutely new, differs in many important details and as a whole, both in principle and execution, materially from all others.

THE PREPARATION OF THE PATIENT FOR THE OPERATION.

The patient should be free from any acute disease, for instance bronchitis, exacerbations of albuminuria or diabetes, rheumatism and the like. His conjunctiva must be reasonably free from pathogenic germs. Dacryocysto-blenorrhœa and chronic purulent conjunctivitis absolutely counterindicate the operation. In dacryocysto-blenorrhœa the lachrymal sac should be largely split and rendered aseptic, and if this be impossible, obliterated before the operation is undertaken. Chronic purulent conjunctivitis has to be completely cured with nitrate of silver and other remedies, even if it takes six months or a year, before an operation of extraction is justifiable.

Preliminary ripening operations are, in my opinion, almost always superfluous. I prefer the risk of extracting an unripe cataract to that of any ripening method with which I have become acquainted. The leaving of remnants behind has, in the manner in which I operate, very little to signify. Locked up in the capsule they produce no iritis, and can easily and successfully be dealt with by the secondary division of the capsule.

I avoid operating on *cataracts swollen by imbibition*. They render the section difficult and rarely come out cleanly, whereas the immature cataracts, known under the name of nuclear sclerosis, if the anterior chamber is deep, mostly—not always—come out entire.

The patient is placed on an operating chair, opposite a window, or in cloudy weather, near an Argand burner whose light is concentrated on the patient's eye with a hand magnifier. The instruments are carefully cleansed with corrosive sublimate solution 1:5,000, then held in boiling water for a short time, immediately before being used.

The eye is anæsthetized by three instillations of a 4 per cent. solution of cocaine, fifteen, ten and five minutes before the operation. The lids and surroundings are carefully washed with soap, then with corrosive sublimate, with which also the inner surface of the upper lid is washed by means of a pledget of absorbent cotton. From the first instillation of cocaine until the commencement of the operation the eye is kept closed. The patient is subjected to no preparatory treatment, except a bath and thorough cleansing of his face and head. Each patient is examined when or before he enters the hospital, whether his internal organs are healthy, in particular his nerve centers, lungs, heart, digestive and urinary organs.

The operator stands behind the patient's head, operates on the right eye with his right hand (upper section always), on the left eye with his left hand. The lids are kept apart by a wire speculum. I prefer the Moorfield's speculum, or one which Tiemann lately made for me, both being modifications of the large Graefe speculum, preventing the ends of the branches from pressing on the eyeball by its own weight, the long curved parts of the branches hanging down and resting upon the temple.

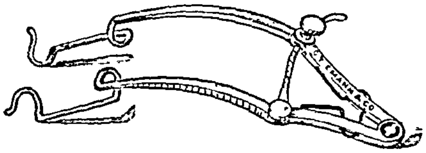

Figure 1.

The eye is steadied by the operator, who implants the teeth of a fixing forceps with his free hand into the conjunctival and episcleral tissue immediately below the lower edge of the cornea. When the speculum is applied, and before the eyeball is steadied, a drop or two of a 1:5,000 solution of mercuric bichloride is let fall on the eyeball.

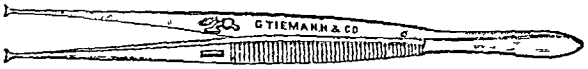

Figure 2.

EXECUTION OF THE OPERATION.

The *most important step of the whole operation is the corneal section.* For full-sized cataracts it comprises exactly the upper half of the cornea, for smaller, Morgagnian, and soft cataracts somewhat less. A perfect section passes in its whole extent exactly through the transparent margin of the cornea, the knife (see Figure 3) remaining in the same plane throughout, particular care being taken that in completing the section the blade of the knife is neither turned forward nor backward. In many cases a small, central conjunctival flap is formed which, if anything, is an advantage.

Figure 3.

This section is distinguished by its accurate and firm closure. It does not favor prolapse of the iris as the peripheric section does, nor does it lead to slow healing, secondary infection, and adhesions or incarcerations of the iris, as the more central flap often does. By cutting the lamellæ of the cornea *obliquely the contents of the eyeball*, by pressing the posterior lip of the wound toward the anterior, at once seal the section, so that the patient can move, open and shut the eye without disturbing the wound.

I open the capsule by passing the delicate sharp lance of the *cystotome* behind the iris from the nasal to the temporal side, thus incising the capsule near its periphery, parallel to the corneal section. This mode of cystotomy leaves the centre of the capsule unbroken and prevents the adhesions resulting from the contact of a torn and bruised pupillary edge of the iris with shreds of capsule and remnants of lens. The expulsion of the cataract and the clearing of the pupillary field can be done through the peripheric opening of the capsule as well as through the central.

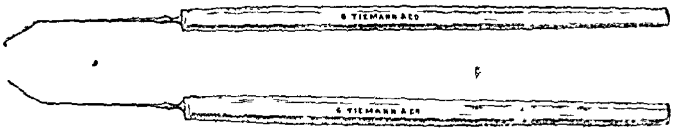

Figure 4.

I confine the removal of a piece of the anterior capsule to the thickened central portions of hypermature cataracts. I again and again have tried to remove the anterior capsule with forceps, a procedure that has become rather popular in Europe and has some warm advocates also in this country, but I have not found it so advantageous as to adopt it for all cases. It may be possible to *remove* a piece of capsule, not merely to *lacerate* it, and in this way to obtain a clearer pupil than by the extensive laceration of the capsule, but the result, as far as I have experience, will be simple posterior synechiæ in many cases and plastic iritis with its consequences in some, and the posterior capsule, to which the remnants of the anterior are agglutinated, mostly dots and wrinkles in the course of months and years, with corresponding falling off of sight.

Figure 7.

Among the *accidents of the extraction of the anterior capsule* I may mention that in some cases when the capsule is tough the piece torn out is not limited to the pupillary space but extends to the equator of the lens, in others the whole crystalline body is drawn out. In both events the vitreous chamber is opened, a lesion which extends the wound and favors the occurrence of prolapse of the iris.

Of the many modifications of the original Liebreich or Mathieu forceps, the essential feature of which consists in the position of the teeth on the surface and not on the tip of the branches, I prefer the one Tiemann made for me and which I described two years ago (*Arch. Ophthalmology,* 1890, p. 288). When the instrument is closed, the teeth are hidden and the instrument is smooth all around. In this way the branches are introduced into the eye without scraping at the iris or raising the cornea perceptibly. When the branches separate, the teeth on the lower side project, and when pressed again together grasp so much of the anterior capsule as is desired. The forceps close only at the end, between the teeth, so that the iris is not included. Dr. Eugene Smith has so modified this instrument, that the tooth bearing ends are sunk slightly below the straight prolongation of the branches, thus dipping readily into the pupillary space. The instrument is well devised but a trifle bulky, and is not so readily introduced as the one spoken of before. I have tried it once only.

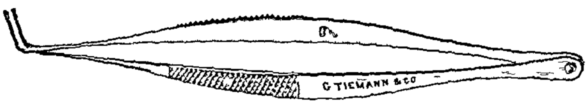

Figure 5.

Figure 6.

The *expulsion of the lens* is effected by pressing the lower part of the cornea, with a Daviel's spoon, directly toward the centre of the globe. When the lens presents in the gaping section its exit is aided and followed up by slight strokes with the spoon on the outer surface of the cornea, so as to expel the lens, together with its cortex, as a whole. Should the pupil not readily expand, the rigid sphincter portion is drawn backward with the wire loop which is held in the other hand of the operator to aid in the expulsion of the lens. Should the section prove *too small* it is enlarged at one end with a pair of strabismus scissors, which also serve for cutting the iris in iridectomy, just as the capsule forceps serves in grasping and drawing out the iris for the same purpose. In the majority of cases the cystotomy and expulsion of the lens can be done *without* keeping the eye steadied with the fixing forceps. In restless people and pro-

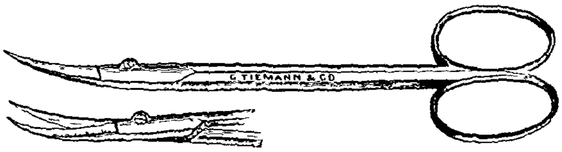

Figure 8.

lapse of vitreous I remove not only the fixing forceps but also the speculum immediately after the corneal section, and expel the lens by external pressure with the lids. I scarcely ever have to resort to the wire loop or any other traction instrument to get the lens out.

The *clearing of the pupil* is effected almost exclusively by pressing with the edge of the lower lid on the cornea. The remnants are wiped away with a well sterilized highly polished curette; neither the edge of the upper lid nor that of the lower is allowed to get in contact with the wound. The so-called milking manœuvre, by which the remnants were formerly pressed into the wound and *wiped out of it with the edge of the upper lid is highly reprehensible*, this procedure being as nearly a direct inoculation of germs as is possible. Equally reprehensible is it to introduce a curette or spoon into the anterior chamber to scoop remnants out immediately after such instrument has been passed over the cornea to expel the lens. There are germs on the cornea and conjunctiva even after the most careful disinfection. They are taken up by the spoon and carried into the anterior chamber. No instrument that enters the eye should have touched any living tissue, including the fingers of the operator, the skin of the lids or the conjunctiva of the patient.

Figure 9.

During the operation I repeatedly let some drops of a 1-10,000 solution of corrosive sublimate fall on the wound and its surroundings, and when the operation is completed I smooth out the conjunctival flap, if there be any, introducing the end of a polished grooved spatula (*see Fig. 6*), previously moistened with the above sublimate solution into the anterior chamber and passing it through the wound from one end to the other, stroking from within outward, in order to remove particles of lens, redress a curved-in flap, and carefully adjust the edges of the wound.

This is, however, not done before *the iris has spontaneously or artificially recovered its natural position.* Should the corneal section be too peripheric, the best thing is to make a small iridectomy at once, for peripheric (Graefe's) sections commonly lead to large and harmful prolapses. If the iris does not spontaneously resume its position, frequently it does so when the lower part of the cornea is pressed upon with the edge of the lid. This paradoxical phenomenon may thus be explained. The iris being pinched in the tightly closing wound, pressure on the lower part of the cornea raises the flap and disengages the iris which then, by its natural elasticity and contraction of the sphincter pupillæ, can resume its natural position. If this encheiresis fail, the iris should be pushed back with a spatula into the anterior chamber. When the periphery of the iris remains folded in the sinus of the anterior chamber, it is smoothened out with the olive tipped point of a probe (see Fig. 9) introduced into the iris angle, behind the opaque corneal margin.

Formerly I washed the anterior chamber out with a solution of biniodide of mercury or boracic acid, but gradually this procedure has fallen into desuetude without appreciable influence on the results. I can say the same of instillations or eserine or pilocarpine after the operation. *When the operation is finished*, and the patient can open and shut his eyes without disturbing the flap on the iris, I drop a few drops of 1-10,000 bichloride of mercury solution on the wound and into the conjunctival sac and *let him go to bed without any bandage*, holding his eyes open or shut at his pleasure. The nurses help to undress, he lies down and closes his eyes. In from 5 to 20 minutes I inspect the eye again, and if everything is all right I bandage it. The *dressing* consists of a patch of moistened corrosive sublimate gauze, and a pad of moistened absorbent cotton fastened with two strips of isinglass plaster. The non-operated eye is covered the same way for a day or two. In nervous, old, or timid people the good eye is barely covered by a patch of gauze, fastened over the brow by a strip of plaster. The patient is instructed to keep both eyes gently closed and use the good eye only for eating and calls of nature. The first day the greatest possible rest is recommended. From the second day old people may sit up a part of the day. Since September 1891, I have followed this practice of letting the patients go to bed with their eyes unbandaged in 125 cases. In one of them I found the pupil displaced. I stroked the iris back, but there was a prolapse of iris when the eye was opened on the fourth day. In two of them I found an iris prolapse which I cut at once and obtained a smooth healing. Having in this way satisfied myself that in the other cases, the patients had stood the transportation from the chair to the bed and the undressing without a tendency to prolapse, was less in dread of this event, yet it occurred in a few instances, mostly by some accident.

Ordinarily there is pain for 5 or 6 hours after the operation, then the eye is and remains quiet. If after hours or days of freedom from irritation the patient, by an injury, a fit of coughing, or other more or less violent exercise, or without any assignable cause, feels a sudden sharp pain in the eye which gradually dies out in an hour, then in all probability a prolapse of iris has occurred. If I am informed of it within several hours, I open the eye, and in case the supposition prove true. I cut the prolapse, reducing the edges of the iris, if there be no irritation, *i.e.*. the prolapse is simply mechanical. If I notice the prolapse later, on the third or fourth day, I leave it untouched. Some of the small ones disappear, others skin over and produce no irritation, others become larger, constricted at their base or cystoid. I leave all these until the irritation has disappeared, and then cut them off. This operation, when performed after the eye has become white, is nothing more than the amputation of a small staphyloma and is usually followed by a smooth and permanent recovery.

For a time I wanted to *test the practicability of dealing with the iris-prolapse, under all conditions, as soon as it came to my notice.* The majority of cases did well, but there were three most unfortunate ones, the only failures I have had from iris prolapse whether operated on or left alone. Those three cases were one loss by suppuration, and two losses by irido-cyclitis chronica, both followed by sympathetic ophthalmia, so that both eyes became blind.

The first (extraction, with removal of a portion of anterior capsule), a man of 76 years, had a prolapse on the fourth day, when the eye was opened for the first time. It was excised the whole length of the wound. The next day no reaction, but on the temporal side there was a small angular incarceration, with a small bead of vitreous presenting.

Six days later the incarcerated portion had become bulging and was abscised. Infiltration of the wound developing into panophthalmitis followed. The patient had chronic conjunctivitis.

The second had a large prolapse cut on the fourth day, as soon as it was noticed. Edges reduced. Clean iridectomy, no irritation the following day. In the next night he struck his eye, causing some incarceration. Slow irido-cyclitis developed, followed in third month by iritis in the other eye. Both eyes were lost. Patient suffered intensely from rheumatism, and his eyes have given him a great deal of pain for a year after the operation.

The third case was a complicated (cholesterinic) cataract in a man of 71. Extraction with a portion of anterior capsule. On fourth day small prolapse noticed in outer corner; abscised 20 days later. Slow irido-cyclitis. Strings of cholesterine in vitreous adherent to scar. Fifty-four days after extraction the first circumcorneal injection noticed in other eye. In six months closure of both pupils. S=1-00.

These excessively sad cases are depressing in the highest degree. Their disheartening effect is counterbalanced only by the overwhelming number of good results.

The patients are usually discharged at the end of the second week. By this time the irritation has usually disappeared. The pupil almost always is free from adhesions, but sometimes more or less obstructed by remnants of lens. The capsule stretching across it may be smooth, dotted or streaked. The average visual acuteness in the third week is $\frac{20}{70}$. For the next two or three months the vision frequently becomes a little sharper, but then it gradually and steadily declines, so that S. as high as $\frac{20}{40}$ or $\frac{20}{30}$ in the sixth week may be reduced to $\frac{20}{200}$ and even $\frac{10}{200}$, without any subsequent inflammation, but simply by dotting, thickening and wrinkling of the capsule. This course has been the rule, not only in my own operations, but also in those of other operators, so far as their patients have come to my notice.

Excepted from this rule are: 1. Those cases in which the lens has been removed in its capsule. 2. Those in which secondary capsulotomy has been made. 3. A moderate number of those in which a part of the anterior capsule has been removed. 4. A small number of those in which the center of the anterior capsule has been extensively lacerated during the extraction. Having watched these results in hundreds of cases, I have made for the majority of cases the *early secondary discission of the capsule an integral step, the final act of the operation.* Experience has taught me that the easiest and neatest performance, the smoothest recovery and the best permanent visual results may be expected, 1. If the pupillary area is free from products of inflammation. 2. If the secondary changes in the capsule are not too old. 3. If these changes have not yet begun, *i. e.*, during the first weeks or months after the extraction. For years I have practiced the early secondary discission of the capsule as a rule. The results have been so satisfactory that I continue the operation without any material change.

Figure 10.

Figure 11.

The *secondary discission is made with a knife-needle*, the stem of which is so proportioned to the size of the little knife that it stops the opening, admits of passing the needle in different directions through the anterior chamber without letting aqueous humor escape. The operation can be done only under artificial focal illumination.

The needle is commonly introduced at the temporal side of the cornea 2 or 3 mm. from the margin, then its point transfixes the capsule at the inner margin of the dilated pupil. The capsule is first cut horizontally across. Then the needle is passed in front of the lower segment of the capsule, transfixes it near the lower margin of the pupil and slits it by an upward incision. Then the needle is passed before the upper segment of the capsule, which is transfixed at the upper pupillary margin and cut by a downward incision. This is the typical form of secondary capsulotomy, and gives a large and free pupil. Many modifications of this type are needed, for the manner of splitting must be suited to the peculiarities of the case. Each case is a study for itself. We must select the thinnest places, those that offer the least resistance, for the splitting, under all conditions avoid dragging fibrous bands to and fro. A T-shaped incision answers the purpose frequently, a curved incision, passing around a dense part, is often sufficient, but a linear straight incision commonly closes again. We should not thrust the little knife more deeply into the vitreous than is necessary to make clean and sufficiently extensive cuts. Avoid deep ploughing of the vitreous, for there is a dark side in this operation, the importance of which I have learned of late only. I mean the *occurrence of glaucoma after secondary discission of the capsule.* In the April number of the *Archives of Ophthalmology* of 1892, p. 293, I published ten cases from my own practice. Sometimes the first day after the discission, sometimes a few days later, acute glaucoma breaks out, the eye grows painful, red, hard, and rapidly loses sight. Myotics relieve the symptoms, but control only mild forms of the disease. The others have all been cured by a prompt iridectomy. In all, the anterior chamber was filled with vitreous, and this seems to be the permanent condition when the opening in the capsule does not close again or some thin hyaline membrane is formed.

In evidence of this I may mention the case of a gentleman who had been operated on twenty years ago, by repeated discissions of a congenital cataract by the late Dr. C. R. Agnew. In one eye detachment of the retina had followed, in the other there was a round black pupil, increase of tension, glaucomatous excavation, gradual impairment of sight, contraction of the naso-frontal part of the visual field, and some floating opacities of the vitreous. S. 20-50. In this condition he was sent to me by a colleague who had just received and read the above publication. I made an iridectomy with a lance-shaped knife. Immediately after the corneal section healthy vitreous escaped, through which I introduced Tyrell's blunt hook, drew the iris out and cut it. Finding that only the inner half of the iris had been exsected, I at once introduced the hook again, drew the outer half out and cut it close to the sclerotic. Recovery prompt and good.

This has also been the method in other cases, with the difference that our introduction of the hook brought the iris out to the periphery. To try to grasp the iris in aphakial eyes with a pair of forceps is commonly unsuccessful. The iris recedes at the first pressure.

Messrs. Geo. Tiemann & Co., New York, have put all the instruments I use for primary and secondary cataract in a neat little case, which is very handy.
